THE cholera situation in the Philippines is still most serious, in spite of the fact that the time has arrived when the disease should wane and disappear, if this is to occur before the next rainy season. While cholera has practically ceased to exist in the northern part of Luzon, a few cases occur daily in Manila, in spite of every effort; and in the southern islands the pestilence still rages with much violence. In fact, it is in these southern islands that the cholera death rate has attained its maximum. Up to the first of December nearly 80,000 deaths were officially reported to the sanitary authorities as having occurred in the islands as a result of cholera; and of this number about 3,000 have occurred in the city of Manila. These official figures, however, are undoubtedly much too low, and it is safe to say that in the neighborhood of 140,000 persons have perished from cholera during the nine months it has been present in the Philippine Islands. In many instances the only records of deaths in the smaller towns are kept by the friars, who classify nearly everything not actually homicide, under the heading "died from natural causes." In the small country barrios it often happens that no sanitary records, at all, are kept, and it is in just such little towns that cholera has prevailed with the greatest intensity. In many instances not only large towns but entire provinces were without any qualified medical men, and in those towns where quarantine measures were attempted the cause of death was often wilfully misrepresented, in order to prevent discomfort to the survivors and to prevent the destruction of property. For this reason, many native physicians have not hesitated to render false death certificates, thus running up the apparent death rate from dysentery, gastritis, etc., in a most extraordinary manner. Further, the friars have always tried to belittle the situation, and have lost no opportunity of trying to impress the people that the disease was not cholera, and that the sanitary measures of the Americans were thus not necessary. It is obvious also that no record could be made of the ravages of cholera among the savage hill tribes of the interior, or among the hostile Moros in the southern islands. For these reasons it is only fair to estimate that the official returns, as to cases and deaths, should be almost doubled. As the mortality among those affected appears to run in the neighborhood of 70 per cent., it may be considered that more than 200,000 cases of frank cholera have occurred in the islands during the continuance of the present epidemic.

As already intimated, the outlook for the coming year, with respect to cholera, is not reassuring. Every house in Manila is inspected several times daily for the purpose of detecting possible cholera cases, and these, when found, are at once removed to the cholera hospital, and their former surroundings disinfected. The value of this treatment is shown by the fact that but few "contacts" have so far developed the disease—nevertheless, from a dozen to twenty cases are occurring daily, and not a single district of the city appears to be free from the infection. The cases are more of a sporadic nature, and there have never occurred in Manila such virulent and general outbreaks as have devastated Iloilo and other southern towns. Still, cases are occurring constantly, and in sufficient number to show the widespread nature of the infection. Even should the northern islands and Manila become entirely free from the disease during the next few months, the climatic conditions in the southern islands are such that the cholera would, undoubtedly, spread among the Moros and other tribes not yet attacked, whence the infection would almost certainly be reimported into Manila and the northern islands, as interisland communication by the natives in their small boats is scarcely preventable, and this has been one of the chief factors in the extension of the present epidemic. Hence, if cholera exists anywhere in the islands by the first of May next, its extension over the entire archipelago during the coming rainy season may fairly be expected. That cholera infection will still exist in the Philippines at that time is practically certain. It is true that a second outbreak would not entail the widespread mortality of the present epidemic, but its occurrence would be most serious from not only a sanitary, but also the financial and political aspects—the latter being the result of the insufficient crops depending upon the paralysis of industry due to the existence of the disease.

In Manila, at present, the infection seems to be transmitted by food, rather than the water supply, and to be kept alive by the indescribably filthy and insanitary personal habits of the Filipino native. Lazy, indifferent, fatalistic, and deaf to sanitary advice, it would be a most difficult matter, even with abundant funds and ample executive powers, to prevent him from contracting any disease which it might be possible for him to acquire. Like a wilful child, he is impervious to reason and argument, and yields a grudging obedience only under the constant pressure of superior force. It is absolutely impossible for the sanitary authorities to overthrow the domestic customs which have been handed down from many generations. Even if it were possible to place a guard in every house, the guards themselves would, of necessity, be Filipinos, in sympathy with those they were set to watch, and perfectly willing to overlook any infractions of the, to them, unnecessary rules of the Americanos. In addition to fighting disease itself, the sanitary authorities must also contend against national custom, racial instincts, and character, and religious superstition—and the combination is one which would prevent entirely satisfactory results under the best obtainable circumstances. One does not wonder that cholera still exists in the islands, but rather, that all the natives are not killed off by it, when hearing of such cases as, for example, of a woman sopping up the discharges of a cholera patient from the floor, and then plunging her unwashed hands into the common bowl of rice, from which she and the remainder of the family made their dinner. It is by just such uncleanly habits as this that cholera still maintains itself in Manila.

The religious superstitions of these people in relation to disease are also extraordinary, and in these they are supported by the friars—always hostile to the Americans, and anxious to inculcate the idea that the occurrence of disease is purely a sign of a displeased deity, and that it is not only futile, but impious to attempt to control such disease by human means. The practice of medicine is discouraged by the priests as weakening their influence. During the height of the epidemic, charms and amulets against cholera were openly sold by the friars, who gained much money thereby. Later, as the disease declined, the friars attributed this supernatural interference instead of to natural causes and endeavored to show the instrumentality and intervention of the church in bringing about this happy result. For instance, one *padre*, in a northern province, told his congregation that he had had a vision in which he had seen San Roque, the patron saint against cholera, descending into a well, and that San Roque had informed him that whoever drank or bathed in the waters of this well would have no cholera, that he (San Roque) thought that his people had been chastened enough, and had come back to protect them. This announcement was made immediately after the priest had heard that cholera no longer existed in the province. Immediately following the announcement of the priest, the people of the vicinity flocked to the well by hundreds, the news rapidly spread, and within a week a crowd of thousands had collected, many coming from distant provinces and camping in the fields. It was a sight never to be forgotten to see hundreds of men, women, and children, stripped stark naked, standing about the well and having its waters poured over them, while others were drinking the water and carrying it away in bottles. The conditions were present for a most virulent outbreak, for many of the faithful came from districts in which cholera still existed, and the well was certain to become ultimately infected, and prove a focus from which the disease would be transmitted in all directions. Argument was useless with the pilgrims, and it became necessary for the authorities to close the well by force, and place it under an armed guard—for the people firmly believed that San Roque would stamp out cholera, if they only did as the priest told them.

A very serious hinderance to the efficient handling of the cholera proposition is also the lack of a sufficient number of medical men to act as supervisors, and of sufficient funds. A considerable number of volunteer surgeons were placed under the control of the civil government by the military authorities, but these men are soon to be mustered out, and their places have not been filled. Of course, no reliance can be placed on the native physicians, who are not only few in number, but are of a generally low degree of professional merit, and the civil government has not the money to attract and retain many good men in positions under it. Major Carter, the Sanitary Commissioner, is a most excellent man who is doing magnificent work, but it

is quite impossible for him to carry the whole sanitary work of the archipelago on his own shoulders. In Manila he has also had to contend with fraud and dishonesty among his subordinates, as a result of which several of the latter will pass much time in the future behind bars. The sanitary situation is thus highly complicated, and the outlook is, to say the least, unsatisfactory.

Within the next few months the leper colony, planned some time ago, will become an accomplished fact, work having been delayed by reason of the outbreak of cholera. So far, a preliminary appropriation of $50,000 has been made for the work, which is now to be pushed as rapidly as possible. The colony is to be located on the island of Kulion, about in the center of the archipelago, and southwest of the island of Mindoro. The island offers good facilities for proper isolation, the water supply is good, the timber abundant, drainage is excellent, and it possesses an admirable harbor. The soil is fertile, and the climate particularly adapted to rice culture. The present population is estimated at about 800, of which only 300 are fairly civilized, the others being savages. It is now estimated that the number of lepers in the Philippines is in the neighborhood of 10,000, with twice that number of persons belonging to leprous families, though not themselves lepers. To prevent the breaking up of families, both classes will be established on the island, the non-lepers in a separate town, and occasional communication between them will be allowed under suitable regulations. Both classes will be permitted to cultivate land and engage in their ordinary avocations. Those who are able to do so will be required to pay to the Government a small rental for the land cultivated, as it is the purpose of the authorities to make the colony as nearly self-supporting as possible. The purpose is to provide normal homes, eliminating, as far as possible, the repulsive features of the disease. The lepers will be allowed to organize and control their own government; select their own officers, and make their own laws, subject to such restrictions as the Philippines Commission may consider necessary. Marriage of lepers is to be prohibited, and the men and women will be kept apart, separate schools being provided for boys and girls. It is hoped that through this colony it may be possible to ultimately eliminate leprosy from the islands. It is understood that Dr. de Mey, a former volunteer army medical officer, now in charge of the San Lazaro leper and venereal hospital in Manila, is to be the first medical superintendent of the new colony.

OUR ALBANY LETTER.

(From Our Special Correspondent.)

POLITICS IN THE STATE SOCIETY—HOW PRESIDENTS ARE CHOSEN—THE BENEFITS OF THE FOUR YEARS' COURSE IN COLLEGES OF THE STATE—THE DOCTOR OF PUBLIC HEALTH.

ALBANY, February 2, 1903.

NARRATION of the incidents leading up to the selection of the present President of the Medical Society of the State of New York shows how much harm is being done to the cause of science by the strife, which, for so many years, has estranged medical men in the State of New York. While there is no written rule or regulation which makes necessary any geographical considerations in the annual selection of the society's president, there has, for years, been a tacit understanding that New York City should have the presidency every third or fourth year, and that the western, middle and southern tier, should also be recognized in rotation and in order. With this arrangement it has become difficult for Kings County, even occasionally, to edge in with presidential timber, of which it naturally always has an abundance. Thirteen or fourteen years ago Brooklyn had her last president, and last year it was conceded, in decency, that the City of Churches was "past due," and the wishes of the delegation were consulted as to whom they most desired. They had agreed upon a very excellent physician, but unfortunately for their ambitions, when he was "weighed up" by the physicians of the State generally, it was concluded that he was not heavy enough, and they asked for another name. "Our own choice, or no Brooklyn man!" was the slogan of the member of the nominatting committee, and "no Brooklyn man" was chosen. This year, of course, Kings County was again told by all interested, "Choose a good man, and we will elect him unanimously." Accordingly a caucus of the Kings County delegates and members was held previous to the meeting of the State Society, and after a contest, a well-known practitioner of Brooklyn was selected as standard bearer. At Albany it developed that the prominent members of the society throughout the State had reason to suppose that the selected Brooklynite had been flirting with State Medical Association men; that he had been guilty of so conspiring with others to amend the constitution and by-laws of his county medical society as to recognize the code of ethics of the American Medical Association, and practically to forswear allegiance to the State society. Of course, such a man could never be permitted to be the head of the State society—again, it would not be fair once more to relegate the claims of the Brooklynites to the rear and select a president from elsewhere. The nominating committee, grappling with the novel situation, concluded, on learning from the Long Island contingent who might be considered an alternate, finally agreed on the man now occupying the presidential chair. A popular man from the southern tier received six of the nine votes, the second choice received two votes, and the Kings County man, slated by them, received his delegate's one vote. And so the committee reported the two nominees having the largest number of votes in committee (as per the society's by-laws); but when their report had been read, the southern tier nominee, mindful of Brooklyn's right to the presidency, withdrew his name, and a Brooklyn physician, untainted with association affiliations, was unanimously elected president of the society. For two days and two nights nine of the society's prominent members, who came to Albany to read and discuss papers of scientific value, were compelled to remain in practically continuous session, joining issue with one of their number as to who should be president of the society; for an equal length of time, every Long Island delegate and member was equally busy trying to convince someone or anyone that his was the only righteous candidate for executive of the society; for hours the issues involved were discussed by all interested in the society's welfare, and with the exception of the personal friends of the original Kings County candidate, there was a unanimity of opinion that the man who wrote a letter, which showed that he was tarred with the association stick, although not a member of that organization, even though but over-zealous or indiscreet, was not fit to serve as President of its society at this particular time. So ends another chapter in what is supposed to have been the latest attempt of its enemies to cripple the usefulness of the Medical Society of the State of New York.

It must be gratifying to the sponsors of the existing statute regarding lengthened time of study at a New York medical school, previous to graduation, to note the beneficial effect of this legislation. The enemies of the proposed four years' course of study predicted many and serious losses in attendance at New York medical schools, and some of these latter were alarmed at the promised result. Secretary Parsons of the Regents' office presents figures and facts in his report which show a greatly *increased* attendance at New York State medical schools, undergraduate as well as post-graduate. Merit counts here as elsewhere. A wise parent or a discerning preceptor will advise his charge studying medicine to enroll at the institution affording the best facilities, and will make sure that proper standards are there established and followed. Four years of medical school study is none too much in these times of medical development. With statistics showing a lessened number of licentiates in medicine, and an increased number of students at medical schools in the State of New York, it follows that these schools are assuming a national import, and a study of the roll of attendance indicates that not only out-of-the-State but out-of-the-country matriculants are appreciative of the advantages to be derived from the pursuit of medical study in New York State medical institutions.

The increase of medical students in New York State medical schools is as follows: Cornell University Medical college, 86; Long Island College Hospital, 56; University and Bellevue Hospital Medical College, 20; University of Buffalo, medical department, 20; Eclectic Medical College, 16; College of Physicians and Surgeons, 12; Albany Medical College, 12; Syracuse University, College of Medicine, 12; New York Homeopathic Medical College and Hospital, 10; New York Medical College and Hospital for Women, 4.

The report of the State Board of Medical Examiners representing the Medical Society of the State of New York shows that during the past eleven years (since establishment of license law) the average per year of those applying for license has been as follows: Homœopaths, 46; eclectics, 16; regulars, 576. A closer study of the figures shows that the greatest number of homeopathic candidates (68) appeared in 1899; of eclectics (30), in 1899, and of regulars (809), in 1898.

The suggestion made that the post-licenciate title of Doctor of Public Health be established by legal enactment in the State of New York, seems to have found ready echo among the officials of the Medical Society of the State of New York at the annual session, just concluded. Retiring President Hopkins asked the society to advocate this action; Dr. Heffron's report of the Committee on Hygiene referred favorably to the same proposition, and President Potter of the State Board of Medical Examiners, in presenting the annual report of that body, came out in loud

praise of such legislation. Is there not sufficient in all this to justify the society's committee on Legislation in framing a bill embodying this idea for presentation at the present legislative session?

THE EXPLANATION OF THE CASES OF YELLOW FEVER ON BOARD THE S. S. PLYMOUTH.

To the Editor of the Medical Record:

Sir: The explanation by Dr. W. C. Gorgas of the cases of yellow fever which recurred on the S. S. *Plymouth*, in the Medical Record of October 4, 1902, has been quite a disappointment to me.

Seeing his name as the author of the article, I started reading it with eagerness, feeling sure that since he was presenting an explanation, he would certainly have a reasonable and acceptable one which would enlighten those who are earnestly seeking enlightenment.

But after reading not very many lines it is found out that the reader starts on the *supposition* that mosquitos were on board the vessel and hibernated on it. Now, those who know how scarce specimens of Stegomyia fasciata (the only kind of mosquito that is infectible) are on board of vessels at ports quarantined against yellow fever cannot but be mighty slow in accepting their intermediation unless supported by positive facts. The proof of the scarcity of the stegomyia on board of these vessels will be given by the present writer in a paper which is now under preparation.

Further on the distinguished sanitarian says that it was reported that flies had been seen crawling out of cracks between planks. The presence of flies must, of course, be accepted, but no mosquitos are mentioned, simply because there must have been none, otherwise they would surely have been named as the flies have been.

After attempting to prove that some mosquitos had resisted all the treatment which the *Plymouth* had been put through, Dr. Gorgas finally sees the unreasonableness of the explanation and says: "It would be very unusual for the stegomyia, as we know her here, to escape the cold and disinfection, as described with regard to the *Plymouth*." The doctor then goes on to say that he believes that the cases were not yellow fever.

Dr. Gorgas wrote to Dr. Carlos Finlay and to Dr. Juan Guitéras for an expression of opinion. Dr. Finlay says: "Regarding the diagnosis of the two cases on board of the *Plymouth*, I see no reason for doubting its correctness." Dr. Guitéras replies: "It appears to me that it is difficult to explain (the cases), no matter which of the theories of the etiology of the disease we may maintain." Hence we must conclude that there is a lack of harmony among the prophets. Edmond Souchon, M.D.

New Orleans, La., January 27, 1903.

MULTIPLE PREGNANCY WITH A VENGEANCE.

To the Editor of the Medical Record:

Sir: On December 22, 1902, I was called to attend Mrs. C. Escorza of Florence, Cal., in premature confinement (eighth month), at which her mother, a Mexican of perhaps fifty-seven years, was present, and stated, with perfect confidence in the truth of her assertion, that at two of her own several pregnancies she had aborted about the second or third month, at each abortion passing seven fœtuses! Before understanding the date of the abortion, I asked whether any of the seven lived, to which she replied in the negative, adding with a smile of amusement that there was not room enough, hence the early abortion. She could not recall what doctor attended her, but said the case was so unusual that the specimens were sent to Europe. I recall having treated this woman, whose name is Luiza Silva, for pneumonia about three years ago. R. C. Shultz, M.D.

Los Angeles, Cal.

Etiological Relation of Tonsillar Angina to Appendicitis.—Hans Weber reviews the literature and adds three cases which confirm the views of the other observers, which tend to show that many cases of appendicitis are accompanied or preceded by a tonsillar angina. None of these three cases went to operation, and the diagnosis of appendicitis, therefore, rests upon the clinical symptoms present. The latter, however, were sufficiently characteristic to admit of a positive diagnosis. In the first case the tonsillitis preceded the appendicitis by seven days. In the second the appendicitis first appeared during an attack of tonsillitis. In the third both conditions appeared simultaneously.—*Münchener medicinische Wochenschrift.*

Progress of Medical Science.

The Boston Medical and Surgical Journal, Feb. 15, 1903.

Diet in Typhoid Fever.—Frederick C. Shattuck says that from 1886 to 1893 his hospital patients were given an exclusive milk diet until the temperature had remained at or below 99° for a week; since that time he has fed his typhoid patients according to their digestive power rather than according to the name of their disease, simply avoiding anything which contains, or can reasonably leave a residue irritating or harmful to the ulcerated surface. Under the exclusive milk diet he had a mortality of 10 per cent. in 233 cases; with the enlarged diet the mortality has been 8.45 per cent. in 246 cases. Relapse was less frequent, hemorrhage, and perforation no more frequent than among milk-fed patients. The patients are more comfortable and have a shorter convalescence.

Typhoid Fever in Private Practice.—J. T. H. Nichols says that a suitable, sunny room should be chosen without too much regard to the convenience of the household. He urges an abundance of fresh air night and day; even a breeze is not to be feared provided the patient have a screen. An open fireplace will secure the discharge of foul air. If too warm for a fire a kerosene lamp in the fireplace will give an efficient draught up the chimney. The bed should be a single one, preferably of iron, with wire spring, a soft hair mattress covered with rubber cloth, and a double layer of blanket over this. Sheets should be changed and the blanket aired daily the mattress, changed and aired often. If there is room there should be two beds, that the patient may have a daily change with the least disturbance. Cleanliness and the use of means to destroy the germ of the disease should be enjoined. When all these things have been done the question of drugs is of secondary importance.

Paratyphoid Fever and Its Complications.—Joseph H. Pratt describes cases of fever which may present all the classical symptoms of typhoid, but in which the Grünbau-Widal reaction is absent, while from the blood is obtained a bacillus intermediate in type between the typhoid and the colon bacillus. The paratyphoid bacillus may be defined as a member of the intermediate group which produces typhoidal symptoms in man. The disease affects chiefly young adults; it prevails most extensively in the autumn; although a few fatal cases have been reported, the fever is usually mild. The number and frequency of the complications is a striking feature of the disease. The surest way of making the diagnosis is to cultivate the paratyphoid bacillus from the blood of the suspected case. But if the organism cannot be recovered from the blood, urine, fæces, or some localized lesion, the diagnosis is justified, in the light of our present knowledge, if the blood agglutinates a paratyphoid bacillus in high dilution, and fails to agglutinate the typhoid bacillus or agglutinates it only in very low dilutions. There are two kinds of paratyphoid bacilli, A and B, and the blood shoud be tested with both, as in some cases a negative reaction will be given with one and a positive reaction with the other. Eighty-four cases have so far been recorded.

Journal of the American Medical Association, Feb. 7, 1903.

A Note on Malarial Vertigo.—T. J. Mays believes that vertigo is a very much-overlooked symptom of malaria. It may be intermittent or permanent, merely a condition of dizziness or associated with other neuroses, and is attributed to the effect of the malarial poison on the solar plexus. Associated with the vertigo are headache and backache, depression of spirits and exhaustion. The most favorable combination of remedies known to the author is a combination of quinine, pushed to mild cinchonism, and strychnine, blue mass, and capsicum. In obstinate cases of vertigo the possibility of a malarial origin must never be lost sight of.

How Not to Be Nervous.—H. T. Patrick says, if you wish never to be nervous, live with reason, have a purpose in life and work for it, play joyously, strive not for the unattainable, never regret the unalterable, be not annoyed by trifles, aim to attain neither great knowledge nor great riches, but unlimited common sense, be not self-centered, but love the good and thy neighbor as thyself. The time to start such an ideal life is in early childhood. Two capital errors in the training of children are deplored by the author—(1) leading children into pleasures and duties beyond their years and (2) magnifying their importance in the family and in society. It is quite as dangerous to give to children the pleasures of adults as to require of them the labors of the mature.

Cardiac Stimulants.—J. M. Patton discusses the various indications and contraindications of digitalis, strophanthus, sparteine, caffeine, strychnine, and various other

and less used remedies. Nothing new is presented, the conventional lines of argument being followed. Concerning strychnine, he says among other things, that during the second and third decades of life it is not as well borne as it is later, being likely to excite and irritate the nervous system. Mention is made of adrenalin as a cardiac stimulant. (In the discussion following the reading of the author's paper, H. C. Wood, Jr., observed that when given by the mouth adrenalin is too rapidly eliminated to produce any physiologic action on the circulation. It may prove efficient as a cardiac stimulant in acute conditions if used intravenously.)

Medical News, February 7, 1903.

The Facts in a Case of Hæmaturia.—Charles H. Chatwood reports the case of a man of forty years who suffered from hæmaturia for four years with a relatively small amount of deterioration in general health. Microscopical examination of the urine failed to show any evidences indicating the seat of the hæmaturia; but its general character suggested the bladder or prostate. Cystoscopic examination was very satisfactory and disclosed repeated jets of bloody urine coming from the right ureteral orifice. Operation was performed, and the kidney in its general contour and gross substance gave no satisfactory evidence of the cause of the trouble. There was one spot as large as a penny which seemed more dense than the rest of the organ. This was incised and a small piece removed for microscopical examination. The diagnosis from study of the sections was chronic parenchymatous nephritis. There was prompt cessation of hæmaturia following operation.

What Advice Should Be Given to a Woman Suffering from Fibroid Tumor of the Uterus?—J. Riddle Goffe sums up his paper as follows: "The proper treatment for fibroid tumor of the uterus, speaking in a broad way, is removal by operation, and that immediately, whether the tumor be large or whether it be small, whether in a married or in a single woman, excepting only women of very advanced years and those in which the tumor is complicated by pregnancy. In the last the course to pursue will depend largely upon the circumstances and conditions of the individual patient. As a rule, the majority of cases of fibroid tumor of the uterus complicated by pregnancy will go to full term and be delivered normally. In the hands of an expert, Cæsarean section at full term is safer for mother and child than myomectomy during gestation in the rare instances in which such an extremity is required. It is better to take the risk of such a procedure, the necessity of which is very remote, than to destroy the child by inducing miscarriage or taking the risks of myomectomy.

Trap-Drummer's Neurosis: A Hitherto Undescribed Occupation-disease.—Charles J. Aldrich describes this case. The man's occupation was to beat a drum by the operation of a pedal which is manipulated with the right foot, while with his hands he plays the other drums, triangle, and the various traps. Some time ago he began to have a cramping pain and sense of great exhaustion, which seemed to be located in the tibialis anticus and peronei of the right leg. He also experienced a feeling of constriction of the leg as if the circulation had been stopped. Soon after there was a sensation of heat in the kneecap and a painful sensation in the same area. Later there was a burning pain in the knee. This is only apparent while playing or walking rapidly. The writer concludes that the technique of this occupation furnishes all of the necessary elements for the production of an occupation neurosis. It is a series of educated movements, and rare development of kinesthesis in a set of muscles whose centers are very low in the cord and whose volitional stimuli travel farther than any others in the body. These stimuli are complexly derived by the way of the oculocortical apparatus, and by a volitional effort are transmitted to the motor cortex. There is great precision and nicety of irregularity demanded. The treatment is discouraging. The left foot is being used, however, with apparent success.

New York Medical Journal, February 7, 1903.

Astigmatism Cured by Operation.—The case is reported by G. J. Bull whose patient was a woman, aged twenty-seven years, complaining of headache and eye strain. She was wearing on the left eye a concave spherical glass, 0.50 D., combined with a concave cylindrical glass, 1 D., axis vertical; and on the right a concave spherical glass, 1 D., combined with a concave cylindrical glass, 0.25 D., axis vertical. These glasses had their centres widely separated for the relief of exophoria. The ophthalmometer showed me: left cornea 80°—0.8; right cornea, 150°—0.7. Vision with either eye alone was $\frac{6}{18}$. Examination of the refraction showed me that the left eye required a concave cylindrical glass, 1.75 D., axis vertical, which gave V= $\frac{6}{6}$ and that the right eye required a concave spherical glass, 1 D., combined with a concave cylindrical glass, 0.50 D., axis 75°, which gave V= $\frac{6}{6}$. There was also an exophoria of 6° or 8°. The operation consisted in complete (subjunctival) tenotomy of the left internal rectus, care being taken not to cut the capsule much beyond the upper and lower borders of the tendon. Three days later the corneal astigmatism of the left eye had disappeared. Improvement steadily continued so that an astigma of 1.7 D had disappeared and the vision had changed from $\frac{6}{18}$ to $\frac{6}{6}$.

The Modern Aspect of Common Colds.—J. Zahorsky believes that colds are due to pathogenic microorganisms and are contagious. He presents in support of his views the following propositions: (1) Colds run a more or less definite course. If colds were merely reflex congestions, these should terminate soon after the excitant eased. As a matter of fact, colds last from three to seven days in spite of our therapy. (2) The inflammation begins at one point and spreads up and down the respiratory tract. This is a common observation, and very much resembles the dermatitides of infectious origin; *e. g.*, erysipelas. (3) Colds are accompanied by fever and general symptoms. This is especially true among infants. These general symptoms are usually proportional to the extent of the local inflammation. (4) Microscopically, as well as macroscopically, inflammatory changes are found in the mucous membrane. (5) The ordinary secretion of the mucous membrane is soon replaced by a discharge more or less purulent. (6) Specific microorganisms have been isolated from these secretions. Among these, the bacillus influenzæ, diplococcus lanceolatus, Friedländer's bacillus, streptococcus, etc., have been demonstrated. (7) The varying clinical picture of colds speaks for a variety in the virulence and character of the bacteria. (8) Colds are contagious. It is hard to conceive how this clinical fact, so easily demonstrable, has received so little attention in the literature of the past. In schools, asylums, and hospitals this fact is very clearly shown almost annually. In family practice, too, the development of one case after another in spite of care is a very common observation. (9) A relative immunity follows each attack. Were colds merely reflex congestions, these congestions should appear after each exposure. But after an attack the individual will be free from a cold for some time.

American Medicine, February 7, 1903.

Hypodermoclysis in Pneumonia, with Report of a Case.—Maurice Kahn believes that a diminution in the amount of toxin in the system in pneumonia, and the inhibition of its reformation, can best be accomplished by hypodermoclysis. It is well known that subcutaneous infusion of salt solution is invaluable for renal elimination of poisonous accumulations. Probably the best safeguard against heart failure in pneumonia is secured by diminishing the toxins by this treatment. Saline infusion weakens the invading army and gives the phagocytes a favorable opportunity to combat the enemy. The object of treatment should be to bring the toxin-laden blood as near its norm as possible, thus eliminating the danger of pneumonia.

Electrolysis in Eustachian Salpingitis with Stricture: Report of Seventy-five Cases.—Ellwood Matlack states that when an electrode is passed into the tube and meets with a mechanical obstruction so great that further advance is impossible, the passage of a current of a few milliamperes will, in a half minute or so, cause such a shrinkage of the tubal structures as will usually allow further progress with ease. These seventy-five cases which are reported represent applications of electrolysis extending into the thousands, which should be sufficient to allow a fairly accurate estimate of its value. Excluding purely labyrinthine conditions, it has been of service in almost all other forms of deafness, and especially in cases of moderate degree, in which the most pronounced changes were in the tube. The best results cannot be obtained from its unaided use, so this should be supplemented by any other measures that have formerly been found of service. It is especially important to have free access to the tube, and to this end septum irregularities should always be connected and hypertrophies of the turbinals cauterized. The writer uses solutions of iodin, menthol, and camphor, conveyed to the parts by nebulizers, to improve the circulation in the nasopharyngeal mucous membrane After electrolysis has restored the normal caliber of the tube, a further use of vapors to the middle ear after the method of Deuch, will be found of great value. The writer believes that this line of treatment marks a distinct advance in aural therapy.

The Lancet, January 24, 1903.

Cure of Trachoma by X-Ray Tube Exposure and by High Frequency Brush Discharges.—S. Stephenson and D. Walsh have treated a single eye in four cases of severe

bilateral trachoma in children. Two eyes were cured —that is to say, the granulations and conjunctival hypertrophy disappeared and have not returned after a period of several months. The remaining two eyes were greatly benefited, and were well on the road to ultimate cure. The cures were effected by seventeen exposures in the one case, and by six in the other, with an average exposure of ten minutes and a distance of about eight inches of the anticathode from the lid. The good effects were found to be equally marked with closed as with everted eyelids. Twenty-two applications of a mild high-frequency brush applied by means of a vulcanite electrode connected with a d'Arsonval apparatus cured a severe case of trachoma in another patient.

On Reflex Convulsions in Growing Boys and Girls.—Eustace Smith says that it is not generally recognized that nervous seizures, due to pure reflex worry, are seen in children as late as the eleventh or twelfth year. The children are generally of neurotic families, are high-strung, excitable and easily moved to tears, but are not necessarily timid or spiritless. Several typical cases are narrated in detail. Perhaps the most common cause is the retention in the gastroenteric tract of undigested and fermenting food. The children almost always complain of poor circulation and cold feet. Hence they have but little resisting power against changes of temperature, and during the latter the chances of a catarrhal inflammation of the digestive tract are greatly increased. Removal of the offending material from the system is followed by prompt recovery. Another cause of such nervous outbreaks may be adenoid vegetations in the vault of the pharynx, and the author inclines to the view that eye-strain set up by hypermetropia and astigmatism may also prove to be the exciting factor in children predisposed to nervous instability. In any case a moderate irritation, if long sustained, may keep the system in a continual unrest, so that any further irritation, even a very slight one, may lead to a nervous explosion. To consider all such cases as epileptic, as is so often done, is to overlook their cause.

The Surgical Treatment of Rheumatic Fever.—J. O'Conor reports twenty additional cases of rheumatism treated by opening and draining the affected joint. The surgical rules guiding him are as follows, it being premised that the strictest antisepsis shall be observed throughout: (1) do not puncture, but open knee-joints; (2) ligate all bleeding points; and (3) drain, do not cork. Also he insists on the great value of thorough drainage in these cases. In order to carry this properly into effect in operations on the knee-joint, an incision an inch long is made on each side of the joint through the capsule. Through both openings a long closed forceps is passed and a fenestrated india-rubber tube half an inch in diameter is drawn across the synovial pouch, leaving about half an inch of tubing presenting at each wound. Drainage having been thus secured, the joint is washed out every morning with a jugful of warm carbolic lotion (1 in 60), and the tube is generally dispensed with on the third or fourth day. Irrigation of the joint is daily continued until healing no longer permits of the passage of fluid. A little superficial necrosis of wound tissue caused by pressure of the drainage-tube need not excite alarm, as this rapidly disappears under an iodoform gauze dressing. The latter is made fresh for each dressing by immersing pieces of dry sterilized gauze in a solution of equal parts by weight of iodoform, alcohol and glycerine. A little formalin (1 in 500) is added to the mixture before use. In arthrotomy of the wrist- and ankle-joints drainage is attained by a piece of gauze passed into the joint through the open blades of a dressing forceps previously inserted.

British Medical Journal, January 24, 1903.

On the Use of Alkalies for the Relief of Pain.—H. Campbell Thomson corroborates Lauder Brunton's views on this subject. He has recently treated several cases of neuralgia and other peripherial nerve lesions with alkalies, and the pain has apparently been greatly relieved. There was one case of persistent neuralgia which had lasted more than a year and had resisted all treatment. After giving an alkaline mixture, of which ammonium carbonate was the principal ingredient, great relief was experienced. Other cases of neuralgia and one of peripheral neuritis have been apparently benefited by this form of treatment.

Bottle-finishers' Cataract.—William Robinson says that this disease is undoubtedly due to the great light and heat of the furnace at which the bottle-finisher works; the explanation given for the fact that the mischief always begins at the posterior pole of the lens is as follows: (1) The nodal point (which practically corresponds to the optical center) is situated at the exact spot where the cataract begins, and here all the principal rays, of the various pencils of rays, falling on the lens, cross and pass without refraction, so that this point of the lens receives the brunt of all the direct rays, harmful by their intensity and heat from the furnace, and is therefore the point first to suffer injury. (2) All the rays from the furnace, except the direct and principal rays mentioned above, which have fallen on the cornea when they reach the anterior surface of the lens, are again refracted, so that when they reach the posterior surface of the lens they are much more crowded together, and are consequently more injurious there than at any other part of the lens. (3) The bright light of the furnace contracts the pupil so that the iris shields the periphery of the lens at first from damage. The disease can be prevented by workmen wearing dark pure blue spectacles.

Deutsche medicinische Wochenschrift, January 15, 1903.

Spontaneous Recovery from a Tuberculous Peritonitis.—O. Borchgrevink reports a case which shows that tuberculous peritonitis is not necessarily fatal and that spontaneous recovery may take place. The clinical course of the peritonitis was chronic, the symptoms at first being more or less intermittent in character and the exudate accumulating slowly. This was finally evacuated by puncture, following which recovery took place. Two guinea-pigs were inoculated (intraperitoneally) with 75 c.c. of the centrifuged exudate. Both of these animals died of tuberculosis. Three years later the patient died of an acute pulmonary lesion. At autopsy the tuberculous nature of the previously healed peritonitis was amply demonstrated.

Wandering Heart.—Rumpf more than fourteen years ago described a case, under this name, in which he regarded an excessively movable heart as the cause of the symptoms. He now defends his diagnosis against the recent attacks of Schwalbe, Romberg, and Braun. When lying on the back or in the upright position no cardiac symptoms were present, such only being present when the patient lay down upon his side. This proves conclusively that the symptoms of cardiac insufficiency were not due to dilatation of the heart, as has been claimed. By a careful percussion of the heart its change of location with the various positions of the body could be easily demonstrated. When first examined the apex beat was in the sixth intercostal space, but now (fourteen years) later is in the fifth. This does not, however, show that cardiac dilatation was originally present, since by percussion it can be shown that during the intervening time the *entire* heart has been raised in the thorax. While it is possible that a heart may show hypertrophy and dilatation in addition to an excessive movability, it is certain that such was not the case in this instance, and that here the sole cause of the symptoms was the excessive movability described.

Berliner klinische Wochenschrift, January 19, 1903.

Hereditary Persistence of the Ductus Arteriosus Botalli.—De la Camp reports six cases. All occurred in the same family and in the same generation. Two were females and four males. Neither the parents nor grandparents were blood relations. Neither of the parents showed any hereditary or acquired heart lesions. Syphilis was excluded from the family history. The diagnosis of the heart lesion of the children was made on the clinical symptoms, the physical examination of the heart, and the cardiac Röntgen picture.

Urinary Fistula and Carcinoma—L. Lipman-Wulf reports a rare case. The patient was a male fifty years of age, in whom a traumatic urethral stricture had given rise to marked urinary retention and subsequently to urinary fistulæ. An internal urethrotomy was performed and the fistulæ closed. One of the latter, however, remained persistent, and the patient, at his own request, was discharged from treatment. Four months later he returned. Upon examination there was found a tumor occupying nearly the entire perineal region. The tumor had ulcerated the central portion, being covered with necrotic tissue and the edges with flat epithelium. The entire tumor was perforated by a number of urinary fistulæ. The clinical diagnosis of carcinoma was made and subsequently confirmed by microscopical examination. Death took place in about six months. The case is of interest because of the great rarity of carcinomas which develop from the epithelium of the male urethra.

French Journals.

The Question of Mercurial Injections in 1902.—Pautrier states that the majority of syphilographers recommend the employment of injections in the following cases: (1) When the physician wishes to avoid all deceit on the part of the patient. (2) In the cases of former affection of the gastrointestinal canal. (3) In obstinate

cutaneous troubles, in nervous or grave visceral affections. (4) As an element of diagnosis in doubtful cases. In fact, aside from these indications the treatment by injections appears as the exceptional treatment.—*Gazette des Hôpitaux Civils et Militaires*, January 22, 1903.

Two Cases of Epithelioma of the Hand.—Paul Alquier and Halbron report these two cases. Amputation was performed in each case. In both cases the epitheliomata had shown this characteristic that is very exceptional: They developed on the palmar surface and remained predominant there. In one case the growth invaded the whole of the palm, destroying the internal border and reaching the dorsal surface. In the other the tumor was located on the thenar eminence and at the base of the thumb. Histologically, the tumor consisted of a lobulated epithelioma.—*La Presse Médicale*, January 21, 1903.

The Treatment of Scarlatina.—J. A. Le Sage declares that the treatment of scarlatina to-day is considered, to a great extent, under hygiene and the surroundings of the patient. Every patient with scarlatina should be submitted to a rigorous isolation, especially at the time of desquamation of the skin. For these tiny particles can spread the disease far and near. The physicians and attendant sought always to put on linen garments before entering the sickroom, and take them off on coming away from the patient. They should also plunge the hands into an antiseptic solution after each visit. These garments are put into boiling water. After the patient recovers the chamber should be carefully disinfected. The room should be large and well ventilated and the patient confined there as long as the desquamation lasts (thirty to forty days). The throat and nose should receive special attention. As to food, the milk régime—absolutely adhered to—is best in infectious maladies not only to reduce to a minimum intestinal or gastric fermentations, but to assure diuresis, which is so necessary in these cases. Cold drinks should be given in abundance, such as lemonade, etc. Salol, benzonaphtol, benzoate of soda, and calomel are excellent when indicated. If the eruption is slow in appearing, a lukewarm mustard bath will facilitate it. During desquamation, soapy baths, followed by antiseptic unctions, will hasten the process. The eyes and ears shoud be bathed with boric solution.—*L'Union Médicale du Canada*, January, 1903.

The Rôle of Anaerobic Microorganisms in Urinary Infection.—J. Albarran and J. Cottet state, as the result of their careful observations, that in urinary infection from the ureter to the kidney, the anaerobic microorganisms play a very important rôle which has not been previously recognized. This will explain a fact that has been noted but not understood by various workers who have observed it. It is the difference that exists between the results obtained from direct examination of pus on slides and those furnished by the cultures of pus made in ordinary media. In the first instance, the pus most often shows the presence of many microorganisms, while the media remains sterile, or at least show only a few colonies. The reason lies simply in the fact that the technique employed does not allow the anaerobic microorganisms to develop. At other times, on the contrary, the microbes are less abundant in the pus; cultures in ordinary media remain sterile, but those in appropriate media show the presence of anaerobic microbes. These facts show with what reserve we should accept the diagnosis of "sterile abscess." It seems probable that in many cases the apparent sterility of suppuration is the consequence of insufficiency of the methods employed. The bacteriological study of urinary infection, in order to be complete, ought to conform to these discoveries; that is, they should take account not only of the aerobic, but also of the strictly anaerobic microorganisms.—*La Presse Médicale*, January 21, 193.

Annals of Surgery, December, 1902.

A Simple Device for Holding Ligatures.—M. Rubel has devised an apparatus for holding ligatures, as, for instance, in bringing the edges of a wound together when it is desired to pass all the sutures before tightening any. The apparatus which he calls a "segregator" consists of a flat steel bar on which a tempered wire bent to form a row of V-shaped grooves about one-half an inch apart has been soldered. At either end of the bar there is a safety-pin to fasten the instrument to the dressings. The segregator is pinned to the dressings about ten centimeters from the wound and parallel to it. It is, of course, made entirely of steel, so that it can be sterilized without being injured. It does away with the use of clamps, which are always geting in the way, and enables the operator to pick up and tie any ligature he may wish.

Traumatic Rupture of the Spleen.—D. N. Eisenrath reports the case of a boy aged ten years who two hours before being seen had been struck in the left hypochondrium with a monkey-wrench. He fainted, but soon recovered consciousness, and was taken to hospital. When seen nine hours later his pulse was 96°, full and regular; there were extreme pallor, restlessness, and thirst, with evidences of abdominal hemorrhage. Abdominal section revealed the correctness of the diagnosis. The incision was made over the border of the left rectus, which at once exposed the spleen, and an extensive tear was found traversing its lower border, from which there was free hemorrhage. There was also a tear in the omentum. An attempt was made to suture this tear, but on account of the friability of the tissues the sutures would not hold. The spleen was then extirpated without difficulty. The patient seemed to do well for two days after the operation, and the anæmia began to decrease gradually. He died on the third day. Autopsy showed that the cause of death was a septic peritonitis, but that there had been no further hemorrhage.

Removal of an Upholsterer's Tack from the Right Bronchus.—A. V. Brokaw reports the case of a girl of eight years with the usual symptoms of a foreign body in the chest. Five days after the accident a skiagram located the body at the bifurcation of the trachea. Active symptoms subsided and nothing was done till about a month later, when the child was brought to Brokaw, who made another skiagram, which showed the body to be in the right bronchus. An opening was made in the trachea and a large endoscopic tube inserted, but the body could not be seen, and owing to the patient's cyanosis further attempts at removal were for a time abandoned, the wound being left opened in the hope that the body might be expelled by coughing. The wound closed spontaneously six days after operation the body not having been expelled. A few days later the trachea was again opened and thoroughly cocainized and swabbed with adrenalin solution. An electro-magnet was introduced, but, although the tack could be felt, it was too firmly imbedded to be withdrawn by the magnet. Finally with the aid of the endoscope it was grasped by forceps and withdrawn. Recovery was without incident.

Subcutaneous Rupture of the Kidney.—G. E. Dodge reports nine cases, and gives a general analysis of the disease, and gives the indications for non-operative and operative treatment respectively. In simple cases with evidences of only slight or moderate hemorrhage the treatment is expectant. The patient is placed at absolute rest in bed, with milk diet. Ice-bags are applied over the injured loin and abdomen and morphine administered where required for the relief of pain and restlessness. The use of internal remedies for the control of hemorrhage, such as ergot, gallic acid, and lead acetate, may also be tried. Where the employment of the catheter is necessary, either for the relief of retention due to clots or for diagnostic purposes, the strictest antiseptic precautions should be observed. When there is extensive accumulation of clots in the bladder, their removal by means of a suitable evacuator is indicated. Operative treatment has two main objects in view—the control of hemorrhage and the prevention of subsequent septic processes at the site of injury. The cases complicated by profuse extracapsular hemorrhage, either within or external to the peritoneal cavity, and those complicated with injury to other intraabdominal structures require prompt operative interference. The conditions that demand exploratory incision after the lapse of the first forty-eight hours are evidences of continued hemorrhage, persistent anuria, septic symptoms, and a well-defined tumor-mass, independent either of evidences of marked hemorrhage or of a septic process. In the latter case, if no other condition is found present at operation than a mass of extravasated blood and urine, incision is justified, since the removal of such material means the prevention of a possible septic process later. The incision that practical experience has proven best adapted to all cases of traumatic kidney lesion of the class under consideration is the transverse incision of McBurney.

Primary Tuberculosis of the Parotid Gland.—J. Frank reports a case of this nature, and believes it to be the first case recognized in this country. His patient was a child of twenty-two months. Two years after the operation it was in good physical condition. From a study of the cases on record, which are few in number, he offers the following conclusions: (1) The etiology of primary tuberculosis of the parotid gland may be divided into a predisposing cause (a slight injury) and an exciting (bacillus invasion). (2) The process may be diffuse or circumscribed; the latter is very rare. In some cases the gland tissue, in others the insterstitial connective tissue, is the seat of the tuberculous process. Histologically all the elements of a tuberculous process are found. In most of the cases bacilli have been found. (3) The course of this disease, like all chronic infections, is very slow. In most of the cases the enlargement was noticed accidentally, and, on account of its slow growth, no further notice was usually taken. (4) The symp-

tom found in most of the reported cases was swelling of the glands, in the form of either a circumscribed and fluctuating tumor or a more diffuse with occasional soft spots here and there, the skin being usually adherent, red, tense, shiny, and œdematous. As a rule, on pressure the size of the swelling does not diminish. There was no enlargement of the glands of the neck in any of the cases. In most of the cases pain was present late in the disease. (5) The diagnosis, on account of its rarity, the absence of the disease elsewhere, and also the absence of pathognomonic signs, is clinically very difficult. In all cases the diagnosis made before the operation was either syphilis, interstitial parotitis, or malignant growths. (6) The prognosis is very good, the affection being a purely local one. Operative interference results in a permanent cure, as was seen in all primary cases. In many cases temporary facial paralysis resulted, which in course of time disappeared. (7) From the cases recorded we learn that the total extirpation of the gland is not essential to a permanent cure.

Archives of Pediatrics, January, 1903.

A Case of Rheumatic Purpura.—Geo. Montague Swift reports the case of a girl of eleven years who, in connection with rheumatic pains in the knee-joints, developed marked purpura. The upper part of the face and the right cheek were first affected, but the coloration extended to other parts of the body. It was most surprising to see the eruption come and go; in places where a day or two before there appeared to be a submucous hemorrhage, there would be no appearance of discoloration. Salicylic acid was administered, and later changed to calcium chlorid. Pleuritic effusion complicated the condition, but finally the child made a good recovery.

Congenital Dilatation of the Small Intestine.—J. N. Hall describes the case of an infant of eleven months which seemed in every way to be normal except for constantly recurring trouble in obtaining a movement of the bowels. No normal spontaneous motion had ever been passed, but by means of medicines, high and low enemata, electrical stimulation and laxative articles of food, normal stools had been passed every one or two days. The child's abdomen was enormously distended, and in the course of a few days the patient died. At post mortem the first two inches of the small intestines were found to be about two-fifths of an inch in diameter, but it then dilated quite suddenly to a diameter of one and one-quarter to one and one-half inches and continued of this size until two inches before its entrance into the cæcum. This portion was of the size of the first two inches. No other abnormality was found except enlargement of the mesenteric lymph nodes. The author believes that the child died of an intestinal intoxication from the retention of fæces, and that the lymph nodes were enlarged through the irritation of the toxins.

Peribronchitis and Interstitial Pneumonia.—A Jacobi says that the vast majority of cases begin and run their full course in infancy and early childhood. The best preventive against the diseases of the respiratory organs is protection against infections and against colds; that means strengthening of all the integuments, both mucous and epidermic, and mainly the cutaneous, and thereby the general circulation and its innervation. Good air, plenty of good food. Begin to wash the well baby, when about a year old, after his warm bath, with water of 70, 65, 60°, and rub him well until he is dry and thoroughly warm. Diminish the temperature when he is older. Beguided by his strength and weight and preqious habits in selecting the treatment. When the disease is acute, subacute, independentf or complicated, it requires attention to circulation and nutrition, rarely to temperature. Frequent and protracted warm bathing, 95° to 90°, has a better effect in this form than in any other. In other respects the treatment is similar to that of other varieties of pneumonia with one exception; it is not to be forgotten that recent cellproliferation and the recently formed connective tissues are absorbable; iodin should be given early.

The American Journal of the Medical Sciences, Jan., 1903.

Eosinophilia in Pelvic Lesions and in the Vermiform Appendix.—William H. Weir concludes that: (1) Eosinophiles take a prominent part in the cellular infiltration associated with inflammatory and suppurative processes of the pelvic organs. (2) In such conditions they usually occur in the largest numbers in the subacute stage and associated with connective tissue hyperplasia. (3) Eosinophilic infiltration is found in most cases of carcinoma of the cervix, and in almost all cases of pyosalpinx and ovarian abscess. (4) In inflammatory conditions of the endometria eosinophiles occur in small numbers and in but few cases. (5) Eosinophiles represent a large poportion of the cells forming the stroma of the mucosa in the normal and the diseased appendix. (6) In inflammatory conditions of the pelvic organs associated with an eosinophilic infiltration of the tissues, the percentage of eosinophiles in the circulating blood is rarely increased and usually decreased.

Adrenal Tumors.—Paul G. Woolley divides these tumors into benign and malignant. The greater number of the benign tumors of the adrenals belong to the adenomata. Besides this class, there are fibromata, lipomata, nemomata, gliomata, angiomata, and cystomata. The most common adenomata are the small multiple adenomata, the large single tumors being far less commonly seen. The smaller tumors may arise in any zone of the organ. The larger ones usually originate in the cortex of the organ. Although these tumors may be large, they never involve the whole gland, and are usually seen as nodules projecting above the surface of the organ which they occupy. As types of malignant tumors originating in the adrenals, the following have been mentioned: Carcinomata, sarcomata, endotheliomata and peritheliomata. The microscopic appearances of the malignant adrenal tumors vary. Their most noticeable feature is their well-marked tendency to variation in type, due to the remarkable inclination of the cells to metaplastic changes. The writer gives an interesting table of primary carcinomatoid adrenal tumors.

The Pathology of the Tissue Changes induced by the X-Ray: Preliminary Report.—A. G. Ellis gives the following summary of the study of the cases which he reports: There is seen necrosis of cells and trabeculæ of varying degree. In one case there is also marked fatty degeneration. Increase of elastic tissue is seen in the three cases examined both before and after exposure. Fewer areas of lymphocytic infiltration were noted in one case after exposure, and about equal numbers in the others. There is a tendency to occlusion of vessels by deposits on their inner surfaces. This is marked in some instances, not so prominent in others. There is practically entire absence of infiltration by polymorphonuclear leucocytes. While endarteritis is probably induced by the *x*-ray, the accompanying tissue necrosis seems out of proportion to the vessel changes, suggesting the possibility of there being *parri passu* results of the same influence, instead of cause and effect. The presence of immense numbers of cocci and bacilli in the tissues of one case after twenty exposures to the *x*-ray would argue against the possession by that agent of bactericidal power. The pathogenicity of these organisms was not proven. It is important that diseased tissue be curetted or cut away, whenever feasible, before instituting treatment by the *x*-ray.

Paracolon Infections, with Report of Three Cases.—Herbert W. Allen describes the organisms obtained from two of his cases as follows: They were very actively motile, having the morphology and staining properties of bacillus typhosus. The growth on agar and in gelatin was similar to that of bacillus typhosus. Bouillon was diffusely clouded; no surface pellicle was formed after ten days' incubation. A slight trace of indol was formed in Dunham's peptone medium after one week. On potato there was a barely perceptible growth appearing as an increase of the moisture along the line of stroke. Litmus milk was slightly acidified after twelve hours; after one week there was distinct reduction of the acidity, and by ten days the color equalled that of the control. After two weeks there was distinct alkali production. There was no coagulation of milk after four weeks' incubation. The organisms fermented glucose and maltose, with the production of acid and visible gas, but did not ferment lactose or saccharose. The organisms agree very closely with most of the paracolon bacilli heretofore described. As to the agglutination tests, a time limit of one hour was used, and a reaction was not called positive unless there was good clumping and cessation of all motility. In none of the cases was a positive Widal reaction obtained in dilutions greater than 1:10, though tests were made frequently throughout the course of the disease. The writer adds that while no very definite conclusion can be drawn as yet regarding the pathology of the disease, it is evident that we are dealing with an infection quite distinct from typhoid fever.

On Multiple Serositis—the Association of Chronic Obliterative Pericarditis with Ascites, with Particular Reference to the "Pericarditic Pseudocirrhosis of the Liver" of Pick and the "Iced Liver" (Zuckergussleber) of Curschmann.—Aloysius O. J. Kelly states in his recapitulation that in a certain proportion of cases of chronic obliterative pericarditis, ascites is the striking clinical symptom, and leads usually to the diagnosis of cirrhosis of the liver. Whence Pick's designation, "pericarditic pseudocirrhosis of the liver," is not altogether inappropriate. Anatomically, the distinguishing feature of these cases is a chronic fibrous (usually hyperplastic) inflammation of the

several serous membranes of the body—a multiple serositis. The thick fibrous connective tissue that encases and compresses the organs gives rise to an appearance suggesting confectioners' icing—whence the term "iced liver." In the diagnosis of this multiple serositis or of chronic adhesive pericarditis with ascites, especial attention should be directed to the history of a previous attack of acute pericarditis, pleuritis, or perihepatitis; to the early occurrence and subsequent disappearance of the œdema of the legs; to the marked ascites, with little or no œdema of the legs; to the enlarged liver early in the course of the disease, and to the small and distorted, but otherwise smooth, liver, in the later stages of the disease; to the absence or very late occurrence of marked enlargement of the spleen; to the tendency to the occurrence of repeated attacks of pain; tenderness, rigidity, and possibly palpable and audible frictions in the right hypochondriac region, due to attacks of perihepatitis; to the rapid recurrence of the ascites after tapping, and to the physical signs of adherent pericardium—without which the disease is incapable of diagnosis. This obliterative pericarditis with ascites may be distinguished from cirrhosis of the liver; by the aforementioned symptoms and signs of adherent pericardium; by the absence of the etiological factors of cirrhosis of the liver; by the slow, insidious, protracted, and intermittent course of the disease; by the long periods of standstill during which the ascites may remain stationary and the patient in good condition; by the entire absence or the transient presence of slight jaundice; by the absence in most cases of portal congestion and gastrointestinal disturbances—hemorrhage, diarrhœa, hemorrhoids, enlargement of the spleen, marked dilatation of the superficial veins of the abdominal wall, etc.; in some cases, by the association of an enlarged, smooth, and firm liver, with marked ascites; and by the fact that in many cases the patient survives a large number of tappings.

Book Reviews.

Clinique des Maladies du Système Nerveux. Vols. 4 et 5. Par Professeur Raymond. Paris: Octave Doin, 1901.

These volumes, each of 600 pages, attest the energy tirelessness of Charcot's successor at the Salpetrièrè Hospital. The permanent value of such contributions is, probably, not very great. Each volume is made up of a series of lectures, which has been edited evidently with some care by Professor Raymond, and they have the value of the average clinical lecture and of articles in medical journals. In such a work as that before us, the author is not called upon to discuss the matter under consideration in an exhaustive way, such as would be necessary in a textbook or a treatise upon the subject, nor is he compelled to revert to the views of others in considerable detail, or to cite references in accord with, or in substantiation of, his statement. Such volumes are, therefore, particularly an attractive way of putting before the student and the reader the current teachings upon the topics handled.

An extract from the table of contents will give an idea of the diversity of subjects treated by the author. Amongst other subjects in volume 4 are: "Insular Sclerosis in Infancy," "Superior Polioencephalitis," "Double Ophthalmoplegia, in Tabic Patients," "Asthenic Bulbar Paralysis," "Hemiplegia with Muscular Atrophy," "Tabes with Muscular Atrophy," "The Various Forms of Progressive Muscular Atrophy," "Diseases of the Caude Equina," "Juvenile General Paralysis," and "Infantile Myxœdema." While in volume 5 some of the subjects are "Partial Epilepsy, Motor, and Sensory," "The Topography of the Sensory Cortical Centers," "The Psychical Equivalents of Epilepsy," "Focal Lesions of the Quadrigeminal Bodies," "Pseudobulbar Paralysis of Cerebral Origin," "The Differential Diagnosis of Multiple Sclerosis and Hysteria," "The Objective Disturbances in Tabes," "Chronic Progressive Anchylosis" (the name given by Raymond to the disease usually known as Spondylosis Rhizomyelique after Marie), and "Hysterical Word Deafness." Such topics, illustrated as they are by the great wealth of the material at the hospital which Charcot made famous, give the author abundant opportunity to display his clinical erudition.

Clinical lectures lose a great deal of their attractiveness on being printed, and these are probably not exceptions to the rule. The living subject shows the features of the disease in a way that words and pictures cannot. There is a freshness about this series of lectures that is particularly attractive, and one is impressed with the author's facility in handling the subject. They cannot help being of much value to the general practitioner who seeks information of typical forms of uncommon nervous diseases, and who wishes to get an epitome of what is known on the subject. He will find this conveyed in the shape of running commentary on different phases of the disease which the patient or series of patients present, and which are pointed out in succession. To the specialists and the neurologists the volumes are likewise of value. First, as showing the author's point of view; (2) his manner of attack of an obscure disease from a clinical standpoint; and (3) the conception which he puts upon features, clinical or pathological, whose interpretation is not yet satisfactorily made out.

Anleitung zur Diagnose und Therapie der Kehlkopf, Nasen, und Ohrkrankheiten. Zweite vermehrte und verbesserte Auflage mit 130 Abbildungen. von Dr. Richard Kayser in Breslau. Seiten 178. Berlin: S. Karger, 1902.

In the present edition the same arrangement of topics prevails as in the first, issued two years ago, but under the separate headings the progress made during this lapse of time has been incorporated, so that the volume before us is an exponent of the rhinology, laryngology, and otology of to-day. It is made up of lectures for practitioners rather than for either students or specialists, so that the general standpoint is that of clinical medicine. In view of the comprehensiveness of the title and the size of the volume, condensation has been required to a marked degree, yet all has been included that the general practitioner need know for the intelligent handling of the vast majority of his cases.

Outside of this we can hardly see that the book calls for special comment. It belongs to a class that has been enormously swollen in numbers during the last few years. While the personal views of so eminent a clinician as the author are of interest to those following this line of work, it cannot be said that manuals of this kind ever do much more than duplicate existing literature.

Biological Laboratory Methods. By P. H. Mell, Ph.D., Director of Alabama Experimental Station, Professor of Geology and Botany, Alabama Polytechnic Institute. Illustrated. New York and London: The Macmillan Company, 1902.

In this volume the author has brought together in condensed textbook form detailed descriptions of the apparatus and methods used in the biological laboratory. Beginning with an excellent description of the microscope and its accessories, the subjects are taken up in logical rotation and concluded with a chapter upon the polarization of light and its application to biological investigations. Especial mention is to be made of the sections on stains and photo-micrography. The majority of the most important staining methods are described in detail, and in such a manner that they can be successfully applied by one of very limited experience. At the end of the chapter there is given in alphabetical order an enumeration of the principal tissues, etc., together with the methods of staining them, which give the best results. This is especially meritorious, and will save the beginner many hours of useless work. The sections on photomicrography occupy a considerable portion of the book, and are to be commended for the accurate descriptions relative to developing the negatives. Taken all in all, the book fills a decided want, and will be found not only of service to the beginner, for whom it is primarily intended, but also of frequent use to the advanced worker who often feels the necessity of refreshing his memory concerning fundamental details.

Massage and Swedish Movements. By Kure W. Ostrom, from the Royal University of Upsala, Sweden. Fifth Edition. Philadelphia: P. Blakiston's Son & Co., 1902.

In this new edition the author has added ten new illustrations, and has rewritten and enlarged the chapters dealing with practical instruction for giving massage. This little book furnishes the professional masseur and nurse with a valuable textbook on the principles of massage and Swedish movements and their application to various diseases of the body.

A Textbook of Surgical Principles and Surgical Diseases of the Face, Mouth, and Jaws. For dental students. By H. Horace Grant, A.M., M.D. Philadelphia: W. B. Saunders & Co., 1902.

The plan and scope of the work are good, and a concise accurate statement of the essential points of these subjects is much needed in book form for dental students. This book, however, requires much revision before it can be safely placed in the hands of students. Such inaccuracies as surgical fever being the reaction from shock, as erysipelas, not being due to an infection of the

lymphatics with the ordinary pyogenic streptococcus and many others, must be corrected before the student is asked to accept the other good statements that the book contains.

The Practical Medicine Series of Year Books. Volume V. Obstetrics. Edited by Reuben Peterson, A.B., M.D., Professor of Obstetrics and Gynecology in the University of Michigan, and Henry F. Lewis, A.B., M.D., Instructor in Obstetrics and Gynecology in Rush Medical College. Chicago: The Year Book Publishers, 1902.

The subject matter of this excellent little volume is arranged under four parts. Part I, on pregnancy, begins with several pages on the placenta, ten being devoted to an abstract of Webster's Monograph, and six to *deciduoma malignum*. Placenta prævia is discussed under this heading—a new departure and not especially commendable, as we can hardly regard this complication as a "disease" of the placenta. The treatment certainly belongs under obstetric surgery. The same criticism applies to the section on premature detachment. The section on the physiology and pathology of pregnancy offer little that is new, especially with regard to hyperæmesis. Eclampsia is treated quite fully (pages 55 to 73), though it must be confessed that the amount of fresh information bears but a slight relation to the voluminous recent literature. Numerous abstracts of articles on pregnancy complicated with tumors appear, and appendicitis receives considerable attention. Twelve pages are devoted to a careful résumé of recent papers on ectopic gestation. Part I includes one-half of the book.

Part II, on labor, has an interesting section on prophylaxis of infection (an awkward expression). Several paragraphs on artificial dilatation of the cervix seem to be somewhat out of place here. Spinal anæsthesia is well discussed, also occipitoposterior presentations. An interesting section on dystocia from operations performed prior to pregnancy shows the complications of labor following ventro- and vagino-fixation. The concluding sections on traumatisms include rupture of the uterus and laceration of the perineum.

Part III, on the puerperium (pages 177 to 212), is devoted almost entirely to puerperal infection, but injuries to the fœtus are fully treated.

Part IV, on obstetric surgery, is quite meager as compared with the other three. It would seem as if either few recent articles had appeared on this important subject, or else the space allotted by the authors had already been filled. Cæsarean section receives most attention, though a few papers on symphyseotomy are abstracted. In general, the work of abstracting and condensing the large number of articles selected has been well done, though not always evenly. Doubtless this is, to some extent, unavoidable under joint authorship. We have aleady expressed the opinion that the arrangement is not all that could be desired. Undue space is allotted to some papers which possess purely scientific interest. Few comments are made by the authors. This volume, though good, is not equal to the one on gynecology.

Diseases of the Eye. A handbook of Ophthalmic Practice for Students and Practitioners. By G. E. De Schweinitz, A.M., M.D., Professor of Ophthalmology in the University of Pennsylvania; Consulting Surgeon to the Philadelphia Polyclinic; Opthalmic Surgeon to the Philadelphia Hospital; Ophthalmologist to the Orthopædic Hospital and Infirmary for Nervous Diseases. With 280 Illustrations and Six Chromo-lithographic Plates. Fourth edition, thoroughly revised. Philadelphia and London: W. B. Saunders & Company, 1903.

The fact that this work appears in a fourth edition within ten years attests to its popularity and to its value. In this edition the volume of the work is increased by about seventy pages over that of the third edition. The subject-matter has been thoroughly revised in every part. Lantern Tests for Color-blindness, Unusual Affections of the Conjunctiva and Cornea, Vascular Changes Occurring in the Retina, Anomalies of Motility, and Orthoptic Exercises have received additional treatment in this volume. The properties of new drugs that have been introduced into ophthalmic therapeutics are more fully described. The pathology of the eye has received greater attention—in short, the author has spared no pains to bring the work fully up to date and to make it as comprehensive as possible, within the scope of such a volume. The systematic arrangement of the material, the concise and direct method of treating the various topics, and a very complete index enables the reader to acquaint himself with all that the book contains on the different subjects, with a minimum expenditure of time.

The operations are considered in a separate chapter near the end of the book, and an appendix in which the use of the ophthalmometer and the tropometer is explained is added. The name of the author is sufficient to assure the reader that he can depend upon the accuracy of the statements made and that he may safely follow the procedures recommended. We do not hesitate in designating this as one of the most useful works on ophthalmology for the specialist, the practitioner, and the student that has appeared in recent years.

La Profession Médicale au Commencement du XXe Siècle. Par Paul Brouardel, Doyen Honoraire Professeur de Médecine légale à la Faculté de Médecine de Paris, Membre de l'Institut. Paris: J. B. Baillière et Fils, 1903.

The writer emphasizes the prophylactic rather than the curative rôle of the physician of this age. He points out the tendencies and consequences of certain laws which are of particular interest to the medical profession. He speaks of the increase in the number of physicians and the decrease in the number of patients; of sanitary confederations, and of international sanitary conferences.

Medical Microscopy. Designed for Students in Laboratory Work and for Practitioners. By T. E. Oertel, M.D., Professor of Histology, Pathology, Bacteriology, and Clinical Microscopy, Medical Department, University of Georgia. Philadelphia: P. Blakiston's Son & Co., 1902.

Realizing that many of the older physicians have had little or no opportunity for laboratory research, which is so necessary to the complete training of the modern physician, the author presents this concise but clear volume. The science of microscopy is new and is constantly expanding its limits, and many of the books on this subject are so full of details that they are more of a hindrance than a help to beginners. In this book the author usually describes only one method to reach a certain result, as this seems most simple in routine work. Among the subjects treated, are the microscope, the preparation of tissue, bacteria, and bacteriological methods, staining, pathological bacteria, tumors, the blood, variations in the formed elements of the blood, urine, semen, vaginal secretions, cerebrospinal fluid, nasal secretions, saliva, sputum, stomach contents, vomit, and fæces. There is a good index. The book is well calculated to fulfill the purpose for which it was written.

Diseases of the Skin. A Manual for Students and Practitioners. By Joseph Grindon, Ph.B., M.D.; Professor of Clinical Dermatology and Syphilis, Washington University; Dermatologist to the O'Fallon Dispensary, St. Luke's Hospital; Member of American Dermatological Association, etc. Series edited by Bern B. Gallaudet, M.D. Illustrated with Thirty-nine engravings. Philadelphia and New York: Lea Brothers & Co., 1902.

After an introduction, in which symptomatology, etiology, and diagnosis are discussed, the body of the book, consisting of 366 pages, is divided under Inflammations, Granulomata, Dermatitis Blastomycotica, Pinta, the Tineas of Mould-fungus Disease, Animal Parasitic Diseases, Purpura, Hypertrophies, Atrophies, New Growths, Pruritus, Diseases of Glands, of Hair Follicles, and of Nails.

Der Kampf des Tierischen Organismus mit der pflanzlichen Zelle. By Dr. R. Sleeswijk in Alkmaar (Holland). Mit Zehn Figuren im Text. Amsterdam: J. A. Sleeswijk, 1902.

This monograph is written in support of the osmotic character of the immunizing processes, not, however, as regards any one class of the body cells, but as regards the osmotic tensions in all of the various kinds of such cells. The author regards the body as composed of a multitude of cells, all of which are connected and unified by osmotic tension. While, therefore, in infective conditions the cells located near to the site of infection are the first to be involved in the conflict, the increased osmotic tension incited in these cells is soon distributed throughout the body, so that all of the cells composing the same become partners in the endeavors to protect the body against the infecting agent. The first portion of the work is devoted to a description of the anatomical and physiologico-chemical relations between the various body cells, and the remainder to a defence of the author's views, particularly as against those now being advanced by the leaders of the German and French schools. Whatever views one may hold concerning this theme, it is certain that the work makes interesting reading and in portions gives food for serious thought.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held January 22, 1903.

JAMES N. WEST, M.D., CHAIRMAN.

Myomatous Uteri Treated by the Apostoli Method Prior to Extirpation.—Dr. A. STURMDORF presented these specimens. He said that only last year at the German Medical Society no less a man than Dr. F. Lange vouched for the uterus having become smaller after the Apostoli treatment. The speaker said he had an opportunity of following three such cases to the operating table, the period of observation varying from three to eighteen months. The patient whom he had observed personally was a woman having very thin abdominal walls and an enormous diastasis of the recti muscles, thus affording an exceptionally good opportunity for palpation. It was remarkable how the uterine body itself shrunk under the treatment, although the small fibroids on the fundus of the uterus remained of the same size. Another one of the cases had been treated by Dr. H. J. Garrigues, but eventually the woman developed peritonitis, and it became necessary to remove the uterus. The Apostoli method could not be too strongly condemned as a radical treatment for uterine fibroids, and yet it had a certain field in the palliative treatment. The cases referred to would be more fully reported at some future time.

Solid Tumor of the Ovary; Double Uterus and Vagina.—Dr. GEORGE H. BALLERAY presented several specimens. The first was a large solid tumor of the ovary, removed one month ago, from a single woman, forty-two years of age. The report of the pathologist had not yet been received, but from the general appearance it was apparently a sarcoma. The growth was very adherent to the intestine and the abdominal wall, making the operation rather difficult. The woman made a good recovery from the operation. A point of interest in the case was that there was a double uterus and a double vagina.

Fibroid Removed After Delivery.—Dr. BALLERAY also presented a tumor taken from a woman who had passed through pregnancy and had been delivered without special difficulty despite the presence of the tumor. About two months after delivery it became necessary to perform laparotomy. There was some dark serous fluid in the abdomen. The pedicle of the tumor was ligated and the tumor removed. The tumor itself weighed about six pounds. The abdomen was closed without drainage, and the result was very satisfactory.

Uterus Removed because of Profuse Hemorrhage.—Dr. BALLERAY presented a uterus removed from a woman, forty-four years of age. She had borne three children. About eighteen months ago she began to flow rather freely, and the flow persisted in spite of curettage. On admission to hospital she was extremely anæmic and in very bad condition. From the history he suspected carcinoma of the body of the uterus. Owing to the woman's bad condition, an effort was made to check the hemorrhage by tamponade and rest, but it became necessary to remove the uterus. This was done six days ago and the woman had done well since then. The gross appearance of the uterus puzzled him, because it showed no obvious cause for the severe hemorrhage. A second tumor was presented, which had been removed for an unusual indication. The woman had been admitted three times to St. Joseph's Hospital almost moribund from profuse hemorrhage following miscarriage. She was advised to have the uterus removed as a prophylactic measure, and this was done. A third uterus was presented which had been removed by vaginal hysterectomy from a woman, twenty-five years of age. She had had a criminal abortion performed on her, and because of the subsequent profuse hemorrhage had sought relief at the hospital. She had a persistent discharge from the uterus. An attack of peritonitis occurred, which was supposed to be of gonorrhœal origin. The uterus was removed after considerable difficulty.

Tumors on Posterior Surface of the Uterus.—Dr. PHILANDER A. HARRIS of Paterson presented tumors to illustrate the peculiarity some fibroids had of filling the pelvis and lifting the uterus up behind the pubes. Two of these were examples of myofibroma and one of myxofibro-sarcoma.

Omphalocele.—Dr. L. J. LADINSKI presented, on behalf of Dr. Charles Dixon Jones, a specimen of omphalocele. On November 30, 1902, a primipara was delivered of a dead male child, weighing eight pounds, and well developed, with the exception of a deficiency of the abdominal wall. This exposed the contents of the abdominal cavity. There was also a marked scoliosis of the spinal column. With the rupture of the amniotic sac, there was a discharge of dark material like meconium. Further examination showed that an umbilical hernia had ruptured during delivery.

Dr. A. BROTHERS said that the uterine wall appeared to him to be considerably thickened in the first case for which hysterectomy had been done, because of persistent and dangerous hemorrhage. He had seen a similar case, in which the hemorrhage had resisted repeated curettings and even the intrauterine use of steam. Finally, he had been compelled to remove the uterus just as Dr. Balleray had done. When examined by Dr. H. T. Brooks, there was found to be beginning malignancy of the endometrium of the corpus uteri.

Dr. H. J. BOLDT thought the prognosis must be changed with regard to cases of sarcoma of the ovary. A year or more ago he had presented to this section a very large sarcoma of the ovary, which he had removed, and he had just learned that this patient was still alive.

Dr. J. RIDDLE GOFFE said he had been in the habit of leaving one ovary in cases in which there was sarcoma of only one ovary, and he had not had any occasion to regret this course, although he believed the general rule in such cases was to remove both ovaries.

Dr. JAMES N. WEST said he had seen two cases in which an apparently normal uterus had bled so profusely as to necessitate hysterectomy. The uterus in one of these cases had been carefully examined by a competent pathologist, but nothing had been found to explain the persistent hemorrhage.

Dr. GOFFE suggested that in two of the cases reported by Dr. Harris it would have been better to perform myomectomy and save the generative organs.

Dr. HARRIS replied that both of these patients were over forty years of age, one of them having passed the menopause.

Position of the Bladder in Fibroid of the Uterus.—Dr. J. A. SCHMITT read this paper. He said that even when slightly distended the summit of the bladder might still be in the true pelvis. Some time ago he had shown to this section a large myoma which had grown from the anterior surface and had developed high up in the abominal cavity. Low down the projecting myoma had barred the approach to the bladder. Such an imprisoned bladder produced no symptoms, because of the ready lateral distensibility of the organ. In women with a weakened pelvic floor, cystocele and prolapse of the anterior vaginal wall were likely to occur. Sometimes the entire bladder was elevated so that it lay near the upper border of the pubes, a true upward displacement. Pressure of a fibroma upon the bladder or upon the urethra might cause displacement. In the latter condition there were apt to be present symptoms of incontinence and cystitis. An elevation of the base of the bladder with the displacement of the whole bladder upward so that the anterior wall came in contact with the abdominal parietes sometimes occurred. Fibroids developing in the anterior wall of the uterus above the peritoneal fold left the position of the bladder

unchanged, except in those rare cases in which peritoneal adhesions between the bladder and the uterus had formed. Fibroid tumors situated in the lateral wall of the uterus might displace that organ toward the opposite side. The bladder followed such lateral dislocations only to a slight extent. The elevated bladder would push up the peritoneum, and a greater or less surface on its anterior wall, free from peritoneum, would come in contact with the abdominal wall. In cases of elevated bladder from uterine fibroid one would always be able to introduce the finger into the prevesical peritoneal sac for a variable distance. Those cases of elevated bladder in which no prevesical peritoneal pouch was found required a different explanation. They were the result of imperfect extrauterine development. The bladder of the new-born differed from that of the adult chiefly in position and shape. Three-fourths of the bladder projected into the abdominal, cavity, and was embedded in loose connective tissues extending between the peritoneum and the fascia transversalis from behind the pubes as far as the umbilicus. In the upper and middle third of the space the peritoneum was reflected on the summit of the bladder without forming a cul-de-sac. During infancy the bladder was conical in shape; in the course of years it descended and assumed an ovoid or cup-shape. At about the age of puberty the empty bladder lay in the true pelvis and the reflected peritoneum was at the level of the upper border of the symphysis pubis. Occasionally, for some unknown reason, this descent of the bladder did not take place. In such cases the conical shape of the bladder usually persisted.

The Palliative Treatment of the Fibroid Uterus.—Dr. A. H. Goelet presented this paper. He said that the palliative measures were: oophorectomy, cutting off the blood supply and ablation of the uterine arteries, dilatation of the cervix with curettage of the endometrium, electricity and, finally, medication, including the administration of animal extracts. The cases suitable for palliative treatment were: (1) Those in which there was present some local or constitutional condition forbidding the removal of the growth; (2) those in which the patient declined operation; (3) those in which the growth was small or was not producing inconvenience, and (4) in young women when the possibility of removing the growth and leaving the uterus and ovaries behind could not be definitely determined beforehand. Oophorectomy should be limited to women approaching the menopause and presenting intolerable symptoms, such as pain and hemorrhage. In small, sessile, interstitial growths, this operation should be done as a matter of necessity rather than of choice when the removal was not practicable, or the increased risk was not justifiable in the individual case. The ovarian arteries should be obliterated when the ovaries were removed as a means of relief in cases of uterine fibroids. The cutting off of the blood supply through the uterine arteries was proper in cases of small interstitial fibroids situated below the fundus of the uterus. Curettage should only be done with a blunt instrument, or one with a copper edge. Following this, the cavity should be freely irrigated with hot water or salt solution, and afterward with a solution of iodine and hot water. Iodine in full strength should not be applied to the endometrium; the strength should be half to one ounce to the pint of water. Electricity would arrest the hemorrhage when the electrode could be brought in contact with all parts of the endometrium. It would also relieve, in a measure, the congestion of the uterus, and diminish the blood supply to the growth. In suitable cases it would bring about a considerable reduction in the size of the growth, and occasionally true myomata would eventually disappear after prolonged electrical treatment. Sometimes electrical treatment would favor the extrusion of the tumor. In the subperitoneal and submucous fibroids electricity was powerless for good. Its use should be limited to small interstitial growths which were not large enough to rise above the umbilicus. The results from electrical treatment were not always permanent; it was advisable to make the application of the galvanic current directly to the endometrium. The faradic current was only useful to relieve the pain in some cases. Iodide and bromide of potassium were useful sedatives in some of these cases. Extracts of the thyroid and of the mammary gland were said to exert a decided action on some of these cases, but his experience with them had been negative.

Operative Treatment of Fibroid of the Uterus.—Dr. Brooks H. Wells read this paper. He said that as there was a definite mortality from the radical treatment of fibroids this was only indicated when there was persistent hemorrhage or pressure symptoms were present; when there was complicating tubal disease, and occasionally because of the nervous excitement and worry caused by a knowledge of their presence. The palliative treatment was practically covered by curettage, which might require to be repeated several times at intervals of a few months. The vaginal operation was indicated when the tumor was situated in the cervical region, but fibroids in this location were rather rare. Intrauterine fibroid polypus when small could be removed through the dilated cervix; when too large for this they might be removed by a T-shaped incision in front of the cervix and division of the anterior wall to the necessary extent. Even large tumors could be removed by this route by the process of morcellation. The wound in the anterior uterine and vaginal walls should be sutured after the removal of the tumor. The presence of pus tubes was a strong contraindication, and demanded a vaginal hysterectomy. For large tumors he preferred the abdominal route. When operating through the vagina one should always be prepared or an abdominal operation, as it might be unexpectedly demanded at any time. The mortality after vaginal hysterectomy should be almost nothing if infection could be guarded against, and yet, according to his experience, the mortality was greater than from the abdominal operation. Abdominal myomectomy was the ideal operation, yet in many cases it was not practicable. It should be remembered that any injury to the capsule of a fibroid would cause troublesome bleeding. The tumor having been freed from adhesions, was lifted from the pelvic cavity, and pedicle ligated in such a way as to occlude the ovarian arteries and the adjacent large venous trunks. The ovaries should be left outside of the ligature unless so diseased as to demand removal. The uterine arteries should be carefully ligated close to the cervix, first on one side and then on the other. Immediately after a hysterectomy a high enema of decinormal salt solution should be given, and repeated in a few hours if there was much shock. Formerly it was the custom to withhold water by the mouth, but he had recently found that these patients did very well if given water by the mouth freely, there being no trouble after the first vomiting, which washed out the stomach and prevented further trouble. If there was much intestinal distention salines should be administered quite early. The patient could usually be allowed to lie on her back or her side. The main causes of death were hemorrhage and sepsis, or general peritoneal inflammation with intestinal atony. In the hands of skilled operators the mortality varied between four and eight per cent. The chances of a secondary infection seemed to be slightly less when the cervix was removed, yet in his hands the supravaginal operation had given the smoothest convalescence and the best ultimate results. Drainage was only used when it was impossible to cover large denuded areas. He had done 106 hysterectomies for the removal of fibroids with four deaths.

Dr. Mary A. Dixon Jones said that by the operation of myomectomy a diseased uterus was left behind to develop more tumors. She declared that there never was a tumor of the uterus that did not give rise to symptoms. The cervix in every fibroid uterus was diseased, and in every such case the uterine appendages were also diseased;

hence, the best treatment was the removal of the whole uterus. She was of the opinion that a great deal of time was lost in tying arteries; total hysterectomy should be associated with very little hemorrhage.

Dr. Boldt said that he had been deeply interested in the very practical paper presented by Dr. Schmitt. He had tried the method of ligation of the uterine arteries in many cases, but had been disappointed with the results. Furthermore the tying of these arteries per vaginam was not very easy. If they were tied with two ligatures it was necessary to go some distance from the cervix, thus running great risk of injuring the ureters. The electrical treatment seemed to him of benefit in such a few cases that it was not worthy of further consideration. Occasionally the hemorrhages could be controlled by hydrastis and by thyroid and mammary extracts. The only really valuable palliative treatment was curettage, and this was not practicable in a great many cases, because of the tortuous state of the uterine canal. It was rare that he felt justified in advising operation for a small fibromyoma, because such tumors rarely caused trouble. He had formerly been of the opinion that total hysterectomy was better than supravaginal hysterectomy, but he now believed that there was the same mortality from both operations, and there was this disadvantage with a total hysterectomy, it was not at all infrequent for scar tissue in the roof of the vagina to give rise to such severe dyspareunia as to make life a veritable burden. Zweifel had led us to believe that the higher the uterus could be amputated the better the prognosis for the patient with regard to the appearance of neurasthenic symptoms. He had adopted this plan, and believed it was a good one, for the prognosis as to life was just as good as where amputation lower down was done, and as regards the condition of the patient after the operation he felt convinced it was decidedly better.

Dr. P. A. Harris was of the opinion that the field for the use of the curette was very limited in cases of large fibroid. The hemorrhage was probably due to attrition, or possibly to endometritis; hence it did not seem rational to resort to curettage. He had seen death occur in two cases as a result of the use of the curette.

Dr. E. J. Ill of Newark said that for a long time he had had no sympathy for the palliative treatment of uterine fibroids, unless it might be the use of certain medicinal measures in a few cases. He objected to any operation which left a mutilated organ in the abdomen. He did not like myomectomy for the removal of a large number of subperitoneal tumors. There were certain cases, especially those characterized by the presence of interstitial tumors, in which the animal extracts had given him excellent results. He had seen the hemorrhage lessen to such a degree that the patients conceived and went on to the full term of pregnancy, and subsequently the tumors were absorbed. He did not think sufficient stress was laid upon the absorption of these tumors which occurred not infrequently after pregnancy, and many of these women became pregnant after suitable medicinal treatment of the fibroids.

Dr. Goffe concurred in the views that had been expressed with regard to the use of the curette, and particularly as to the danger of laying bare the endometrium as referred to by Dr. Harris. His own experience with the animal extracts had been quite different from that of Dr. Ill, as he had observed no benefit whatever from their use. Possibly this was because he had been skeptical regarding their value, and had not kept them up sufficiently long. Mention had been made of the absorption of fibroids after pregnancy, but nothing had been said about the difficulties and dangers of a pregnancy complicated by fibroids. He made it a rule to advise all women with fibroids, whether these were large or small, to have an immediate operation for their removal. Small tumors could be removed by the vaginal route with absolute safety; when the tumor was large enough to rise above the brim of the pelvis the abdominal operation should be done. Cases which he formerly believed could only be relieved by hysterectomy he now thought could be successfully treated by myomectomy. Dr. McCosh of this city had recently reported a series of cases, in three of which, although a number of tumors had been removed by myomectomy, the patients subsequently became pregnant and were delivered of living children. Dr. Wells was to be congratulated upon the wonderful record he held for operations on uterine fibroids. He would differ with him regarding the delivery of the tumor through the abdominal incision before the application of the ligatures. By ligating the tumor *in situ* and then delivering it it was possible to make use of a much smaller incision. It was important to sew over the stump and raw surfaces simple flaps of peritoneum, thus shutting off the cervix and avoiding infection.

Dr. W. Evelyn Porter said that some years ago when the operation of myomectomy was severely criticised he had operated by this method a number of times, and with good results. In young women the operation was indicated in all cases in which a comparatively healthy uterus could be left behind. After the age of thirty-eight or forty it was often wiser to do a hysterectomy. The fact should not be lost sight of that many patients, after the artificial menopause, suffer more than from the fibroids, for which they originally sought treatment. When the tumors were low down and submucous, extirpation from below could be very successfully done. At one time he had presented to this section a tumor, about the size of a full-term child's head, which he had removed by morcellation. The patient's condition after this operation was certainly far better than after hysterectomy.

Dr. Le Roy Broun said that he did not think much benefit could accrue from the curetting of a fibroid uterus, and there was some danger of rupturing of a large venous sinus superficially situated. He had known this accident to occur in the hands of a surgeon who curetted as a preparatory step to further operation. The woman lost so much blood from this cause that she died on the operating table. At times a complete hysterectomy was far safer than a myomectomy, especially if the tumors were numerous, were deeply situated, and approached the uterine mucosa. The surgeon must be the sole judge as to which operation should be selected in the individual case. Of course, myomectomy was the ideal operation. About two years ago he had collected and analyzed 150 cases, and this analysis showed that the lowest death rate was from total hysterectomy with complete through drainage. At that time he had stated that the death rate from total supravaginal hysterectomy was largely attributable to infection through an open cervical canal. Acting upon this thought, he had adopted the plan of closing over this source of infection, and for the past year and a half there had been only uninterrupted recoveries in his hysterectomies. He believed the cervix should be closed in order to exclude this source of infection; certainly in some of the cases analyzed the bad result had been due to sepsis entering through the open cervix.

Dr. G. H. Balleray said that many years ago he had done oophorectomy for fibroids with what was considered fairly good results. In some cases the hemorrhage had been completely relieved, and some of the tumors had disappeared. However, it was not always an easy operation, the ovaries being situated deeply and below the tumor. He had seen two expert English surgeons fail in this operation. He would mention curettage in these cases only to condemn it. To check hemorrhage, a simple tamponade was often useful, if only to get the patient in proper condition for operation. As regards the fear of conception occurring in a woman with fibroids, he would say that he saw no reason for the general practitioner's becoming hysterical over this subject. He did not believe that unless the tumor were situated low down near the cervical region, thus offering obstruction to the descent of

the child, there was much need for apprehension if pregnancy should supervene. According to his experience, the supravaginal hysterectomy was the better operation.

Dr. S. Marx said that the remark that had been made in this discussion relative to pregnancy's taking place after myomectomy led him to say that not only had pregnancy been known to follow this operation, but the pregnancy under such circumstances had been known to terminate in rupture of the uterus. He objected to an extensive myomectomy in persons likely to become pregnant. He had obtained no good results from the medicinal treatment, except from very large doses of stypticin. He had no sympathy with the palliative treatment of fibroids.

Dr. A. Brothers protested against multiple myomectomy, and reported a case in which the first result had apparently been excellent, and yet some years later the uterus was filled with fibroids of larger growth than in the first instance, and they gave rise to more urgent symptoms.

Dr. E. H. M. Sell asked if it was to be taken for granted that many of these cases did not require operation at all. All present must know that there were many patients with fibroids who required no treatment, and who were not even conscious of the presence of the fibroid until their attention had been directed to it by something else.

Dr. West spoke of some cases of fibroids that he had treated by myomectomy. Four of them were women in the child-bearing period, and the operation was done largely with the object of overcoming sterility. One case in which the myomectomy was very extensive had a perfectly normal labor.

Dr. Goelet said that his individual preference was for operation in cases of fibroids, but there were cases which were inoperable, not only because of some constitutional or local condition preventing it, but because the patient often declined operation. For this class he would recommend electrical treatment. It was not always easy through a small incision to isolate and ligate the uterine artery; the easiest way was to find the pulsating vessel, apply a clamp, and ligate on either side of the clamp. He was strongly in favor of myomectomy, particularly in young women. If hysterectomy were done it should be by the abdominal route.

Dr. Wells said he wished to be understood as believing that the curette had a very limited use in cases of fibroid. He had personally used it in only five or six cases, and these were women near the menopause and having a small interstitial fibroid. Myomectomy was not a new operation by any means, but it had become less popular as the operation of hysterectomy had been perfected, and its attendant mortality had fallen from over 25 per cent. to almost nothing. Dr. Baer of Philadelphia and Dr. Goffe of this city deserved the credit for having introduced the improved technique by which these better results had been obtained. In many cases he found it necessary to divide the tumor quite extensively before it could be lifted out of the cavity. It was often necessary to divide the tumor boldly and quickly before the vessels could be secured. He had observed no permanent results from the use of animal extracts. He had seen two cases in which fibroids had been absorbed after pregnancy, whereas he had observed quite a number of cases in which fibroids had grown very rapidly during pregnancy and had undergone some involution afterward. Silk should not be used in the abdomen; properly prepared and not too coarse catgut was to be preferred.

Officers Elected.—Dr. L. J. Ladinski was elected chairman and Dr. C. F. Adams secretary of the section.

Dr. Nothnagel, professor of clinical medicine and therapeutics at the University of Vienna, has been nominated a life member of the Upper House of the Austrian Parliament.

Lord Lister has been created by the King of Denmark a Knight Grand Cross of the Order of Dannebrog on the occasion of his jubilee.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, Held January 19, 1903.

Alexander Lambert, M.D., President.

(*Concluded from page 160.*)

Significance of Oxaluria.—Dr. J. Bergen Ogden read a paper on this subject. He said that oxalic acid might be regarded as a normal constituent of urine, though present in very small quantity. It existed in the urine in combination with calcium as calcium oxalate, which was ordinarily held in solution by the monosodic acid phosphate. Whenever the production of calcium oxalate was excessive, this became insufficient to hold it in solution, and hence crystals were found in the urinary sediment. Properly speaking, the term oxaluria should only be employed in those cases in which the oxalate of lime crystals were present for a considerable period. A few large, primary crystals might be of far greater importance than a large number of small secondary forms. The continued presence of the crystals always showed an overproduction of calcium oxalate, which, in turn, pointed to some underlying pathological condition. One cause was fermentation in the gastrointestinal tract. Dr. Helen Baldwin had produced experimentally in dogs a pronounced oxaluria by feeding these animals on meat and large quantities of cane sugar and glucose. The oxaluria thus produced must have been brought about by other conditions, as, for example, a concomitant gastritis. Up to the time of this research we were without a satisfactory explanation of the cause of oxaluria in many cases, and the treatment was consequently attended by unsatisfactory results. We had yet to learn whether the proteid element was essential, and also whether these fermentative changes and the consequent oxaluria could be brought about by the ingestion of carbohydrates alone. Another cause of oxaluria which must be borne in mind was the ingestion of articles of food containing oxalic acid, *e. g* sorrel, rhubarb, tomatoes, asparagus, spinach, onions, cabbage, and some varieties of grapes and apples. It had been claimed that oxaluria was sometimes produced by the ingestion of fruits containing citric acid. Rhubarb and spinach probably constituted the chief causes of oxaluria arising from articles of food.

The tests for indoxyl in the urine were an index of the amount of fermentation taking place in the bowel, and there was found to be a more or less definite relation between oxaluria and an excess of indican in the urine. A distinction of some practical value was the division of the crystals of oxalate of lime into primary and secondary. The primary crystals were those which had separated from the urine inside of the body, and usually consisted of the large octahedral and most of the oval and dumb-bell forms. The secondary crystals separated after the urine had been voided. They were usually the very small octahedral forms, and perhaps a few of the circular, oval and dumb-bell crystals. The primary crystals often produced more or less marked irritation of the urinary tract, especially if they separated in the kidney itself or in the bladder. Blood globules were often an accompaniment of oxalate of lime crystals in the urine. If the renal pelvis were irritated in this way the examiner would usually find in the sediment some of the caudate cells supposed to be characteristic of this region along with blood cells; if the irritation were in the bladder there would be present some of the squamous cells and round cells of that region.

Oxaluria and Diabetes.—There appeared to be a rather close relation between diabetes mellitus and oxaluria. The latter was probably referable to the gastrointestinal fermentation resulting from an excessive carbohydrate diet or the abundant ingestion of meat in a nitrogenous diet. Not infrequently a marked oxaluria was associated with nervous disorders.

Hyperacidity of the Urine.—Dr. Thomas W. Hastings

read this paper. He said that this subject had chiefly received attention in books published twenty or thirty years ago. In these books some cases of incontinence of urine in children were ascribed to this cause. Normally the urine showed decreased acidity a few hours after meals, the so-called alkaline tide—the decrease being in inverse ratio to the acidity and quantity of the gastric juice. A meat diet tended to increase the acidity of the urine. The normal acid reaction was not due to free acid, but chiefly to the primary salts of phosphoric acid. Of the total phosphoric acid for the twenty-four hours, 0.6 would be due to the primary, and 0.4 to the secondary salts. The precipitation of uric acid did not necessarily mean that the urine was excessively acid; such a precipitation occurred with all degrees of acidity and of specific gravity. The reaction to litmus paper gave no idea of the acidity, the best method was similar to the one used for determining the acidity of the gastric contents. This method gave roughly the excess of the acid equivalents over the basic equivalents. In estimating the acidity, urine not over a few hours' old should be used. A hyperacid urine showed marked acidity throughout the twenty-four hours—in other words, there was no well-marked alkaline tide, and, therefore, it was of no importance at what time in the twenty-four hours the specimen was taken for this examination. Clinically it was found that hyperacidity of the urine caused a certain number of cases of enuresis and some disturbances of micturition.

Prognostic Value of the Diazo-reaction in Tuberculosis.—Dr. Frank C. Wood presented this paper. He said that from 1884 until the present time very little had been written upon this subject, but recently interest in the subject had revived. He had found an opportunity to study this reaction in a large number of progressive cases of tuberculosis in St. Luke's Hospital. This paper was based on 363 cases, of which 117 died. In eighty-one, or 69 per cent., the diazo-reaction was well marked and continuously positive before death. In twenty-two, or 18 per cent., a positive reaction was obtained during a large portion of the time, but disappeared shortly before death, or was occasionally irregular—in other words, about 87 per cent. of the fatal cases showed a positive reaction during the last few months of life. Of the fourteen remaining cases showing no reaction, ten presented symptoms of chronic diffuse nephritis, and two of these died from the kidney lesion. Of 208 mild and non-progressive cases, 188, or 90 per cent., of those examined for over four weeks showed no reaction. Twenty other cases gave alternating reactions. It was found that the reaction might be continuous and strong for a month or two, and then disappear for a short time only to reappear later; yet during this time the condition of the patient might grow steadily worse. The occasional occurrence of the diazo-reaction did not necessarily point to a grave prognosis.

Prognostic Significance of Albumin in the Urine.—Dr. Edward W. Lambert read this paper. He said that one of the first symptoms of disturbance of the renal function was the presence of a greater or less quantity of albumin in the urine. In his opinion, no healthy person had this substance in the urine, but it by no means followed that its presence indicated severe or incurable organic disease of the kidney. Very excessive heat or cold was apt to allow albumin to pass into the urine, but this perversion of function would right itself when the weather changed and the nervous tone returned to the normal.

Dr. Lambert said that from 1868 to 1888 he had been engaged daily in examining the urine of applicants for life insurance, and the rejection of applicants found to have albuminuria had been a means of saving enough money to the insurance, company to pay the entire expenses of the medical department of New York City. According to his experience, few men passed six months without an occasional albuminuria, and the passage of tube casts in the urine. Mention was made of a case, which had been followed for a considerable time, in which no albumin could be found in the urine if this were examined before noon. The quantity of albumin was no index of the gravity of the case. In recent years the microscope had been called to their aid, with the result that it had led to confusion, worse confounded because it had shown the very frequent presence of all sorts of tube casts. Many of these were found too often in persons otherwise healthy to warrant the conclusion that they pointed to serious organic disease. The essential point after all was the manner of life of the person. Great business strain, the abuse of alcohol and tobacco, and the excessive yielding to the animal appetites were important factors.

Dr. S. Oakley Vanderpoel said that in his life insurance work he was confronted daily with this important and puzzling problem. The only way of reaching a satisfactory conclusion seemed to be by determining the percentage of mortality in any given class of cases. In order to arrive at this it had become necessary to divide the cases into groups, *e. g.* all the cases rejected in the past fifteen years because of albuminuria. In this investigation they had been surprised to find the large number of these applicants who were still alive. It was found that classing all albuminurics in one group the percentage mortality was decidedly increased, there being four or five times as many dead per thousand as an equal number of healthy lives. The groups were then subdivided, and it was ascertained that the mortality was less in those cases presenting a simple albuminuria—a temporary albuminuria, for example, at certain hours of the day. In those cases in which the albumin was accompanied by granular casts the mortality was still greater. Given an individual risk with albumin, it was almost impossible to determine which of two men would live the longer, but the mode of life of the applicant would guide one in determining the prognosis in the individual case.

Significance of Nucleoalbumin.—Dr. Brandreth Symonds said that the presence of nucleoalbumin had not been fully appreciated as yet by the profession. This proteid reacted with all the tests containing an organic acid, and would even react with heat when the urine was decidedly acid—in fact, the only test with which confusion did not occur was the old contact test with nitric acid. This test was not very delicate, it was true, but if the specimen and reagent were allowed to stand for about fifteen minutes it became nearly as delicate as the others. For life insurance purposes it was necessary to differentiate this proteid from true albumin. According to his experience nucleoalbumin did not appear to be of any serious import, being usually due to some congestion or subacute inflammation of the genitourinary tract. If occurring in a person otherwise healthy he would say it had no significance. These cases afforded a large field for general clinical investigation. If there were much nucleoalbumin in the urine he would look upon the case with suspicion. All true albuminurics should be looked upon as suspicious, for the condition was not a physiological one, although some writers had applied that term to certain of these cases. Unfortunately there was no means of differentiating these transient cases of true albuminuria from the more serious ones until the disappearance of the albumin. All albuminurics must be looked upon as unsound insurance risks, even though in persons under forty years of age the albuminuria was apt to be transient.

Dr. W. Evelyn Porter expressed the hope that physicians generally would be careful not to make light of the occurrence of albuminuria in their patients, and wrongly advise their patients, but would look upon it as a danger signal, and in this way would co-operate with the life insurance examiners.

Dr. Lambert, in closing, said he thought fifteen or twenty years hence sufficient statistics might have been collected to enable life insurance examiners to come to more definite conclusions regarding the significance of albuminuria.

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

SURGICAL ANATOMY AND OPERATIVE SURGERY. By JOHN J. MCGRATH, M.D. Royal octavo, 559 pages. Illustrated. F. A. Davis Co., Philadelphia. Price, cloth, $4.00 net; sheep or half Russia, $5.00 net.

A COMPLETE LIST OF THE OFFICERS AND FELLOWS OF THE AMERICAN SURGICAL ASSOCIATION. 8vo, 71 pages. Wm. J. Dorman, Philadelphia, Pa.

TRANSACTIONS OF THE AMERICAN SURGICAL ASSOCIATION. By RICHARD H. HARTE, M.D. 8vo, 571 pages. Illustrated. Vol. 20th. Wm. J. Dornan, Philadelphia, Pa.

CANCER AND OTHER TUMORS OF THE STOMACH. By SAMUEL FENWICK, M.D. and W. SOLTAU FENWICK, M.D. 8vo, 362 pages. Illustrated. P. Blakiston's Son & Co., Philadelphia. Price, $3.00 net.

SELECTED PAPERS ON OPERATIVE AND CLINICAL SURGERY. By the late WILLIAM STOKES. 8vo, 484 pages. Illustrated. Bailliere, Tindall & Cox, London, England. Price, 10s. net.

A TEXTBOOK OF PHARMACOLOGY AND THERAPEUTICS ON THE ACTION OF DRUGS IN HEALTH AND DISEASE. By ARTHUR R. CUSHNY, M.D. Third edition, 756 pages. Illustrated, 8vo. Lea Brothers & Co., New York.

URICACIDÆMIA; ITS CAUSES, EFFECTS, AND TREATMENT. By PERRY DICKIE, M.D. 16mo, 148 pages. Boericke & Tafel, Philadelphia, Pa. Price, cloth, $1.00.

THE PRACTICAL MEDICINE SERIES OF YEAR BOOKS, VOL. III—THE EYE, EAR, NOSE, AND THROAT. By DRS. WOOD, ANDREWS, AND HARDIE. 12mo, 321 pages. Illustrated. The Year Book Pub. Co., Chicago. Price, $1.50.

The Use of the Rotary Burr in the Treatment of Chronic Suppuration of the Ear.—Sturm finds that the burr is of service only in those patients with wide and short canals, allowing the use of an instrument with a short shank. His burrs vary from a pyriform to a spherical shape, and have a diameter of two to three millimeters. Their blades have a slightly spiral course, and diminish in size as they approach the pole where they terminate. They have a much slower action at the pole than at the equator. This enables the operator to proceed more cautiously when using the pole, as in the removal of superficial necroses, and to work faster in entering the attic, where the coarser part of the burr comes into play when working laterally. General anæsthesia can usually be dispensed with when the burr is used for the removal of necrotic areas from the labyrinth wall. However, when the attic is to be opened, general anæsthesia is advisable. In this operation the burr readily penetrates the thin skin of the ear canal, making section of this tissue unnecessary. Bleeding is usually not severe, yet it takes frequent mopping to enable the operator to see distinctly. For this purpose gauze saturated in a solution of ferripyrin and cocaine is serviceable. The field of operation should be well illuminated either with electric or reflected light. At the completion of the operation the cavity is irrigated, a tampon of gauze inserted, and a bandage applied. The only ill effect of the operation so far observed has been tinnitus, which usually subsided in several days. The advantages of the burr are (1) that an externally visible wound is unnecessary; and (2) that rapidity of action shortens the period of narcosis. While its employment can never entirely supersede present methods of removing the ossicles, it is of great service in selected cases.—*Archives of Otology.*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending February 7, 1903:

	Cases.	Deaths.
Measles	203	10
Diphtheria and croup	369	47
Scarlet fever	278	16
Smallpox	2	..
Varicella	119	..
Tuberculosis	343	174
Typhoid fever	55	12
Cerebrospinal meningitis	..	..

Gastroptosis; a Critical and Clinical Study, with References to 100 Cases.—Albert P. Francine speaks of two sets of factors in the etiology of this condition: (1) The conditions predisposing to enteroptosis. (2) Those directly responsible, or the exciting causes. Under the first set come hereditary predisposition and constitutional weakness. Hemmeter outlines the exciting causes as follows: (1) Relaxation of the abdominal muscles following repeated pregnancies, abdominal tumors, etc. (2) Pressure of badly-fitting clothing, belts, or corsets. (3) Chlorosis, as described by Meinert. (4) Nervous dyspepsia. (5) Displacements of the female genitourinary organs. (6) Curvature of the spine. (7) Enlargement and increase in the weight of the liver by neoplasms, etc. (8) Lastly, traumatism. Gastroptosis is far more common in women than has been generally supposed, and in nearly all women who complain of symptoms of gastric motor insufficiency, the underlying condition is gastroptosis. It is about four or five times more frequent in women than in men. Although it is more common in women who have borne children, and in those with relaxed and pendulous abdominal walls, and in whom diastasis of the recti muscles exists, nevertheless it often occurs in young nulliparous women in whom the recti muscles are closely approximated. It exists at all ages, but is commonest in early adult life. It is, moreover, found in early childhood. Probably enteroptosis and gastroptosis exist more frequently in children than is generally supposed. Indiscretions in diet are a very widespread and important factor in the pathogenesis of gastroptosis. Enteroptosis is generally believed to be the primary factor physiologically, and to precede the gastroptosis. It would seem that the liver is the primary factor in many cases. Runeberg's method of examination—inflation with air through the stomach tube, following lavage—should be employed. Percussion will then outline the organ. The characteristic symptoms of gastroptosis are those of gastric motor insufficiency, plus nervous influences. In the cases in which there is pyloric obstruction, the symptoms are much exaggerated. The writer sums up the indications for treatment as follows: (1) To relieve the stagnation and fermentation, and to increase the motor power or peristaltic activity of the stomach. (2) To furnish support to the stomach and other abdominal viscera, thus relieving local congestion and symptoms of weight. (3) To tone up the general health and mental attitude of the patient. The means at our disposal are hygiene, diet, lavage, and drugs; massage and exercises to strengthen the abdominal muscles; mechanical support, when indicated; and, in bad cases, with exaggerated symptoms, unrelieved by other means, operation.—*University of Pennsylvania Medical Bulletin.*

The Prophylaxis of Certain Diseases Incident to Camps in Time of War.—The three diseases considered by H. G. Geddings are typhoid fever, smallpox, and measles. He says that, to guard against the appearance of typhoid fever in a military command, the following points must be borne in

mind: (1) early recognition and positive diagnosis; (2) absolute disinfection of the discharges of all (hospital) febrile cases; (3) rigid policing and disinfection of all camp latrines; (4) guarding of water supplies from infection, not only by careful prevention of direct contamination, but by foresight in the location of latrines in relation to the sources of water supply; and (5) the employment of every possible means to prevent the multiplication of flies, and the invasion by them of kitchens and messing places. In smallpox the same precautions are necessary, and, in addition, immediate isolation. In large camps or in the field, it may be necessary to burn all articles exposed to contagion. Before returning to duty the patient, after completing the process of cicatrization, should be subjected to an antiseptic bath, particular attention being paid to cleansing the hairy scalp. In camps, measles spreads with the rapidity of a brush fire. Early diagnosis and immediate isolation are called for, as in smallpox. Special hospitals should be used, and the disease treated as a serious malady, for such it is in camp life. Especially is it essential that patients should not be returned to duty too early, or until they have fully recovered their strength, and, in the interest of others, it is urgently recommended that they be not returned to duty until the desquamative process is entirely completed and the patient should be, as in the case of smallpox, subjected to an antiseptic bath, with particular attention to the scalp, beard, and other regions likely to harbor infection.—*Journal of the Association of Military Surgeons.*

Sensations in Drowning.—James A Lowson describes his experience when dragged under water with a foundered ship. He struck out to reach the surface, but only went further down. This exertion was a serious waste of breath, and after what appeared to be ten or fifteen seconds the effort of inspiration could no longer be restrained, and pressure on the chest began to develop. The most striking thing to be remembered was the great pain in the chest, which increased at every effort of expiration and inspiration; it seemed as if he were in a vice which was gradually being screwed up tight, until it felt as if the sternum and spinal column must break. The "gulping" process became more frequent for about ten efforts, and hope was then extinguished. The pressure after these gulps seemed unbearable, but gradually the pain seemed to ease up, as the carbonic acid was accumulating in the blood. At the same time the efforts at inspiration, with their accompanying gulps of water, occurred at longer and longer intervals. The writer's mental condition was then such that he appeared to be in a pleasant dream, but still had enough will power to think of friends at home, etc. Before finally losing consciousness the chest pain had completely disappeared, and sensation was actually pleasant. Consciousness returned, he found himself on the surface of the water (probably from the action of the life-belt), and finally managed to reach shore. His after-experiences are fully described. He hopes that death by drowning will not again be described as a pleasant death.—*Edinburgh Medical Journal.*

Practical Diagnosis of Gastric Ulcer.—A. L. Benedict states that, in cancer of the stomach, we should determine the location, degree of malignancy, tendency to ulceration, scirrhous massing, metastasis to neighboring organs, and the various complications. Among other points in the diagnosis of cancer he gives the following: Chemic changes usually follow cancer, but are not essentially due to it. Hemorrhage is suggestive of gastric ulcer, but of other conditions as well. Urea is diminished in advanced cancers; the red blood cells are reduced to about 2,000,000 per c.mm. The state of the lymphatic system is particularly diagnostic, the nodes about the clavicle and in the axilla being enlarged in fairly advanced cases, and perhaps more especially on the left side. There are two signs which may be considered as fairly pathognomonic. The first is a cadaveric odor (not merely a bad breath) emanating from the stomach. The second is the finding of cancer nests in the stomach contents; but several of these should be found before a positive diagnosis is made.—*Medicine.*

Rheumatoid Arthritis as a Cerebrospinal Toxæmia.—R. Llewellyn Jones says that opinion as to the nature of this disease has for some time past been divided, some ascribing to it a nervous origin, others attributing it to a chronic infection. The author thinks it probable that the whole truth lies in a "combine," allotting causality to the microbe and its toxins, on the one hand, and granting to the nervous system the minor rôle of being the medium through which and by which the clinical phenomena are colored. He describes the researches whose results have convinced him that there is no essential difference between rheumatoid arthritis and Raynaud's disease. Grave's disease is also frequently associated with it. Scleroderma has been noted in association with Raynaud's disease, likewise with Grave's disease, and also with rheumatoid arthritis.—*Edinburgh Medical Journal.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ending February 7, 1903:

THE TREATMENT AND CARE OF CONSUMPTIVES AT THEIR HOMES, AND THE URGENT NEED OF LOCAL SANATORIA.*

BY S. A. KNOPF, M.D.,
NEW YORK.

THE ideal treatment of the sufferer from pulmonary tuberculosis in nearly all the stages of the disease is the sanatorium or institutional treatment, under such climatic conditions as will permit the patient a well-nigh constant sojourn in the open air, day and night, and at all seasons.

The ideal, however, is not always attainable. For this sanatoria must be situated everywhere. Fortunately, with our modern methods of treatment, admirable results have been obtained in sanatoria situated at relatively moderate altitudes, even at sea level, and under climatic conditions which have formerly been considered almost detrimental to a successful treatment of phthisis pulmonalis.

The number of sanatoria for the treatment of consumptives—rich, poor, and of moderate means—is, as you know, as yet very limited. While I am happy to state that there is an extensive propaganda in favor of them, I desire, right at the beginning, to say that we need a great, great many of such institutions.

Conditions, however, exist and will arise with which the general practitioner is confronted which makes the removal of a patient to a sanatorium impracticable and unwise, and in some instances impossible. First, there are, as has been stated, as yet not enough institutions, and there may be no room in the sanatorium to which the physician desires the patient to be admitted, or the patient may have a personal aversion to institutional life. Again the patient may be too feeble to undertake the journey, or the fear of separating himself from his family may be so intense that the physician, not wishing to add nostalgia to all the other troubles of the invalid, hesitates to have him taken away. Lastly, the patient may be intelligent, obedient, and socially so situated that a veritable sanatorium treatment at home can be inaugurated. Then the family physician can replace the sanatorium physician, and a thorough treatment can be carried on from which the same favorable results may be expected as can be obtained in a sanatorium.

In order to do this we must imitate as far as possible all the educational, hygienic, dietetic, and therapeutic measures in the home of the patient which are in vogue in the best conducted institution or closed establishments exclusively devoted to the treatment of patients suffering from pulmonary tuberculosis. In other words, we must have a sanatorium treatment at home.

Now let us see how this may be accomplished.

The educational measures are, of course, the first to be inaugurated. The patient must know that, though he is at home, he is no longer at liberty to do as he pleases, but that his life is to be regulated by the physician in charge. He must be impressed with the fact that from now on he must labor to get well. While, of course, the greatest kindness and forbearance should be exercised, the patient must understand that carelessness with his expectoration will not be tolerated. He must not expectorate anywhere except in a proper receptacle,

FIG. 1. FIG. 2.

FIG. 1.—Elevated Spittoon, entirely of metal. Closed.
FIG. 2.—The same, when in use.

be this a stationary spittoon (preferably elevated), Figs. 1 and 2; a pocket-flask of metal (Figs. 3, 4, and 5), glass (Fig 6), or pasteboard (Figs. 7 and 8); rags or cheap handkerchiefs, which must be carried in a rubber pouch or a pocket lined with impermeable material. The spittoons should be regularly cleaned

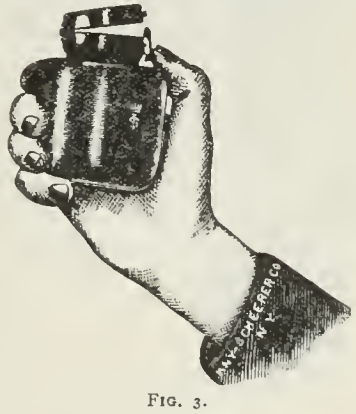

FIG. 3.

FIG. 3.—Nickel-plated, oval-shaped pocket flask. Manageable with one hand.

and disinfected, and the pasteboard receptacles and rags burned after use. If the patient is very much enfeebled, he should have a light mug of aluminum near his bed, to expectorate in, and, if he is helpless, moist rags should be used to receive his expectoration, and the nurse should see to it that

*Read before the New York Academy of Medicine, February 5, 1903.

these rags are burned before they have a chance to dry.

Drop infection should be avoided at home, as it is in sanatoria, and during the so-called dry cough, sneezing, etc., the patient should hold a handkerchief before his mouth. The soiled personal and bed linen of the patient should be handled in the dry state as little as possible, and be boiled before being put with the general laundry. The patient must be so educated as not to cough unless

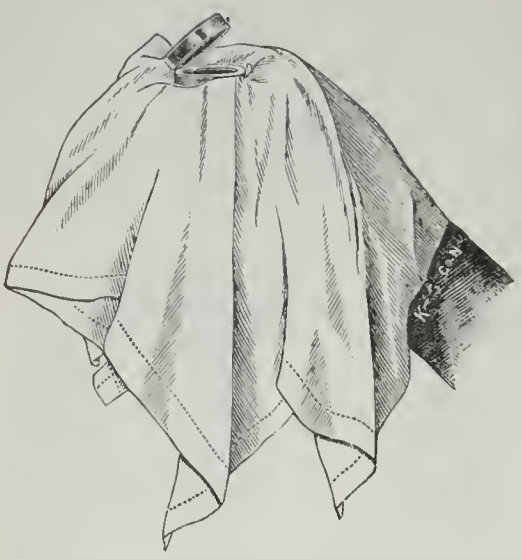

Fig 4.

Fig. 4.—Pocket flask, hidden in the folds of a handkerchief.

he has to expectorate. The yielding to cough because the throat happens to tickle must be considered as impolite at home as it is in a sanatorium, and the patient must learn to discipline himself in this respect. Another point of education I consider warning the patient of the possibility of a hemorrhage. While he should be asked to report any reddish expectoration, or real hemorrhage, he should be taught not to be alarmed at the appearance of a little

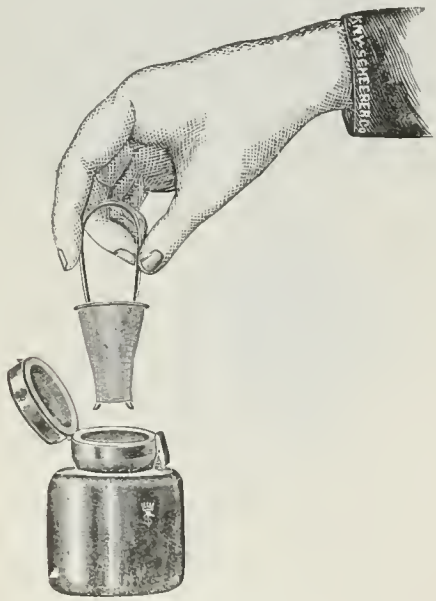

Fig. 5.

Fig. 5.—Method of emptying the flask.

blood, for hemorrhages are a phase of the disease, and do not lessen the chances of cure. Whenever he notices blood in his sputum he should quietly go to bed, take a drink of cold water, or take some cracked ice in his mouth, and send for the physician. Every morning the physician in charge of the patient should make out a schedule of the work the patient has to do during the day: At such an hour he rises, at such time he takes his douche, at such time his meals, at such his walks, at such his breathing exercises, and so on.

Although we should occupy the patient all day with something to get him well, this occupation must be of a nature not to depress him. Thus, for example, I am thoroughly opposed to have the patient take his own temperature every two hours, as is the custom in some institutions. Whenever practical, the temperature should be taken by the nurse or physician. The patient should be kept hopeful and cheerful. Visitors should be allowed to see him, but not too many nor too often. He should be particularly impressed with the rule never to talk to anyone about his disease or symptoms except his physician or nurse, and never to listen to the stories of other patients. The patient should have

Fig. 6.

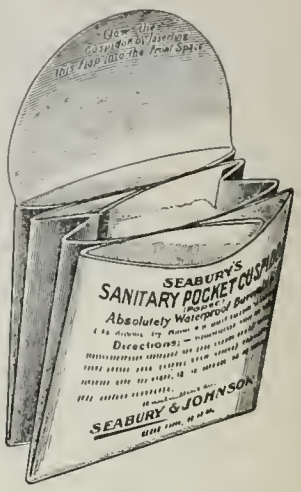

Fig. 7.

Fig. 6.—Blue glass sputum flask. Manageable with one hand.
Fig. 7.—Pocket Sputum purse of pasteboard. Designed by Major Appel, U.S.A.

at least nine hours' sleep, and from half an hour to an hour's absolute rest on the reclining chair before and after his principal meals.

In regard to the personal hygiene of the patient, we must, of course, pay the necessary attention to dress. A consumptive should dress sensibly, comfortably, and according to the season. He should avoid heaping successive layers of clothing

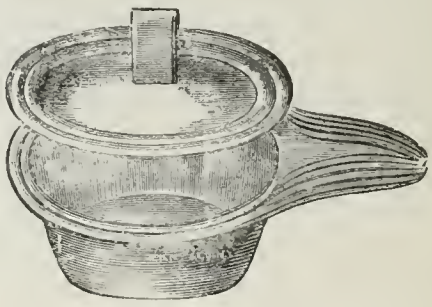

Fig. 8.

Fig. 8.—Pasteboard sputum cup for bedside.

upon himself, especially in the line of so-called chest protectors. These latter, or the numerous woolen undershirts often worn by the pulmonary invalid, are in many cases the very cause of contracting repeated colds by rendering the individual too sensitive. As to what is the most suitable and rational underwear in general, and especially for a consumptive, there is as much difference of opinion among physicians and sanitarians as there is concerning the most disputed points of medicine. To suit the individual case seems to me as essential

here as in other branches of phthisiotherapy. The climate in which the patient lives must be, of course, also taken into consideration. Moderately thick and loosely woven wool of different grades, according to season, has been, perhaps, most frequently recommended for the inhabitants of countries situated in the temperate zone; yet in many portions of Germany, Austria, and Russia sick and well people wear nothing but coarse linen next to their skin. Many people, sick and well, in this country wear cotton, and would not wish to wear anything else; others wear nothing but half cotton and wool; others nothing but silk.

The advocate of any of these systems will be able to say something in favor of his particular one. There seems to be a great deal of truth in what Professor Rubner stated in his article on "Bekleidungsreform und Wollsystem,"* that one can clothe oneself sensibly with other material than wool, if one keeps in view the principles of rational clothing; no overwarm garments and good ventilation of them, homogeneous evenly woven tissues, the layer next to the skin not too thin, and as little difference as possible in conductibility of the tissue in its dry and moist condition. Thus, I believe, so long as our patients do not wear absolutely too warm or too much underwear, we can well afford to let those who are accustomed to wear this or that brand of woolen or half-woolen undergarments abide by it, especially when these patients are in the more advanced stages of the disease. When through a proper course of hydro-, aero-, and heliotherapy the patient has become less susceptible to temperature changes, lighter or different underwear may be thought of. Yet we should be careful in selecting the proper season for such a change, and the most opportune time for a change from heavy to lighter underwear is, of course, when the weather is becoming warmer.

A substance which is not overwarm, as Professor Rubner puts it, and which assures good isolation, would certainly be linen if it could be woven thick and porous enough to meet the other requirements concerning the conductibility in its dry and moist condition, and porosity. Such thickly woven and widely meshed linen underwear has been manufactured in Germany under the direction of that strange genius Father Kneipp, who, in spite of having been an empiric, had certainly some very sound ideas on hygiene. I experimented with Kneipp's underwear on myself some years ago and found that, when one gets accustomed to it, it is, as a rule, warm enough for any season. These garments should be warm enough here, where our houses are nearly always overheated, especially as there are heavier grades made for the winter. When going outdoors, one can protect oneself against the rigorous cold by proper outdoor garments. This linen underwear produces a pleasant constant friction on the cutaneous surface, which counteracts rapidly the first sensation of chilliness which one experiences when the linen touches the skin. As a means of hardening a tuberculous invalid, or as a prophylactic factor in the predisposed individual, I recommend a trial of this or similar kind of linen underwear; but, of course, as I said above, not without having prepared him for the change by cold douches, open-air treatment, etc. Babcock of Chicago, Tilden of Denver, and Ambler of Asheville, have of late become quite enthusiastic advocates of the linen-mesh underwear, which is now manufactured in this country by Dr. Deimel. In a recent paper on the subject, Ambler expresses himself as much pleased with the experience he has had with the linen-mesh underwear with a number of his tuberculous patients.

Consumptives should have warm outer-garments for winter, but not so heavy as to hamper their movements.

Whenever and wherever conventionalism does not reign supreme, the starched linen should be replaced by the light, woolen negligee shirt. It permits better ventilation and freer respiratory movements. Men with a good head of hair need not fear to go uncovered at times, but all, even those with thin hair or bald heads, should not wear too heavy hats or caps, and should always have them well ventilated.

As a matter of personal hygiene, I should, whenever possible, insist that tobacco should not be used in any form whatsoever. There is no doubt in my mind that the congested condition of the mucous membrane of the upper air passages (nose and throat) so frequently found in smokers, is exclusively due to the excessive use of tobacco. Smoking of cigarettes should be considered particularly dangerous for the pulmonary invalid. Patients who are addicted to the use of cigarettes have confessed to me that when smoking they no longer had any desire to breathe deeply. It seems as if the smoke thus inhaled partially paralyzes the respiratory centers.

For women I would recommend the Lady Habberton or Jenness Miller dress-reform. I have described it elsewhere* in full, and only desire here to say that according to the fundamental rule of dress-reform as advocated by the ladies just mentioned, the garments are arranged so that they follow the symmetric lines of the female form, and in all possible cases are made of one piece. All under- and outer-garments are so arranged that the whole weight of them is supported by the shoulders, and no pressure whatsoever brought to bear upon any of the vital organs in either thorax or abdominal cavity.

Tight neckwear should not be allowed to either man or woman. There should be absolute freedom of movement of all portions of the throat and neck.

The hygienic bath, that is to say, a good, hot soap bath once or twice a week, in order to keep the skin in good condition, should be prescribed to the phthisical patient whenever his condition will permit this. In many homes of the poor it will be necessary to content ourselves with the English tub and sponge, instead of the luxurious bathtub.

As to the general hygienic measures which should be practised in the home of the consumptive, much will, of course, depend on the situation of the home and the financial condition of the patient. In the city home of the wealthy a whole floor should be placed at his disposal, and in a country home an extension should be built with an open front to make life in the open air possible day and night. I show you here a picture (Fig. 9) which illustrates the manner in which my friend, Dr. Millett of Brockton, Mass.,** arranges for open-air treatment in a small eastern town. The extension connects with a comfortable, southerly exposed bedroom, and, weather permitting, the bed is rolled outside, so that the patient lives virtually in the open air day and night. Wherever such special arrangements are not possible, at least the

Zeitschrift für Diätetische und Physicalische Therapie, Vol. II, No. 1.

*"Pulmonary Tuberculosis; Its Modern Prophylaxis and the Treatment in Special Institutions and at Home." P. Blakiston's Son & Co., Philadelphia, 1899.

** "The Night-air of New England in the Treatment of Consumption," *Maryland Medical Journal*, January, 1900.

largest, pleasantest, sunniest, best ventilated room should be given up to the patient. Drafts should be avoided as far as possible, but this precaution must not be carried to extreme, so as to make the patient afraid of a breath of fresh air. If the bedroom is too small to make it possible to place the bed so as to avoid the direct draft from the open window, a substantial screen should be used as a protection. The carpet, heavy curtains, and superfluous furniture should be removed without, however, leaving the room cheerless. Small rugs and curtains that can be washed may be retained. There should never be any dusting in the room of the patient; furniture and floors should be wiped off with a moist rag.

The diet of the patient should, of course, be the very best and adapted to his needs. There should not be such a thing as an iron-clad dietary list for a consumptive, and I have long since learned that one has the greatest success by studying the idiosyncrasies of every consumptive, not only in regard to medicinal remedies, but also in regard to diet, and I almost would venture to say that to know what the patient can or cannot digest or assimilate is the keynote to success. My venerable master, Professor Dettweiler, used to say *la cuisine est ma pharmacie* and I think this should be so.

Permit me to read to you the fundamental rules in regard to diet which I give to all my patients: Live on a mixed diet—that is to say, meat, fish, vegetables (especially spinach, lentils, etc.), fresh and cooked fruit, plenty of fresh milk, fresh eggs; all sorts of easily-digested fats (not pork), butter is especially to be recommended. Thick, nourishing soups should be taken with the principal meals. Raw, chopped, or better yet, scraped, beef is especially to be recommended. Whole-wheat bread, being more nourishing than white bread, is to be preferred. Eat slowly, chew your food well, take the milk in small swallows; take but little liquid during and shortly after meals. Never take any alcoholic beverages (wine, beer, or liquor) without special consent and the direction of the physician. Too much sweets (sugar, pies, pastry, etc.) should also be avoided, as well as all kinds of fried food. Take plenty of salt with all your food. Between meals drink plenty of good, pure water. If experience teaches you that any particular kind of food disagrees with you, report it; also report any intercurrent trouble whatever it may be, such as indigestion, diarrhœa, constipation, increased cough, pain, etc. Keep your teeth in good condition by using the toothpick freely and brushing the teeth after each meal.

As it is not the object of this paper to touch on the medicinal treatment of tuberculosis, which certainly can be the same, whether in a sanatorium or at home, I will refrain from mentioning any purely medicinal adjuvants in the dietetic treatment of the consumptive. There is, however, one mechanical means to improve the often-impaired digestion and facilitate natural assimilation, and that is a regular, carefully-applied massage.

To the physician who has tried to practise massage himself it will be known that the bed is the most inconvenient place to perform this operation. To improvise the massage table in a private home, all that is necessary is to place a large board, about five feet long and two feet wide, on the bed and cover it with a moderately-soft mattress and a sheet. You will thus have a good resisting plane on which to place your patient. In view of the fact that we try to overfeed our patient, giving him more to eat than he can assimilate under ordinary circumstances, I look upon massage as a most valuable adjuvant in phthisiotherapeutics.

How can we install a proper aerotherapy at home? I have already spoken of the extension in a country house and the situation and furnishing of the room in the city. But in order to make the rest-cure and the constant life in the open air or in front of the open window endurable, we must seek to make the life of the patient as interesting as possible. The place to put the reclining-chair on which the patient has to remain for hours at a time, should, whenever possible, be so located that the eye looks on something pleasing. A pleasant view, southern exposure, protected against wind, and a dust-free atmosphere is often not easy to obtain, so that the ingenuity of the physician may be taxed to the utmost in order to obtain pleasant and suitable environments, when the patient takes his rest-cure. Occasionally I arrange the flat roof of an apartment or tenement-house for that purpose. I know of a *confrère* who utilized the fire-escape of a tenement-house, but since this is contrary to the law, I do not feel that I can recommend this method of giving the open-air treatment. When it is possible to place the reclining-chair in the garden, yard, or other quiet, open place, such places are to be preferred.

Fig. 9.

Fig. 9.—Permanent arrangement for open-air treatment in a country home.

No matter where the patient sits to take his rest-cure, it should be remembered that he must be comfortable and that the chair on which he lies must be so built as to allow a complete relaxation of all the muscles. He must be protected against cold winds, and he should equally be warned not to expose his head to the direct rays of the sun, to avoid headache and dizziness. His whole body may be bathed by sunshine, but his head should be in the shade. There are many reclining-chairs in the market. The typical sanatorium chair, of which I show you a picture (Fig. 10), has a comfortable bend under the knee and the back can be inclined to suit the patient. In the homes of the poor we often must replace the costly reclining-chair by a cheap, not uncomfortable steamer-chair. When in the garden, yard, or on the roof, the patient can be conveniently protected against the wind, sun, and also against the gazes of his neighbors with the help of a beach chair of wicker work, such as are used in fashionable seaside resorts. By taking out the seat and lining the inner walls with

padding, and then placing the reclining-chair inside, the patient is completely protected.

Another way of facilitating the outdoor rest-cure is the construction of a sort of half-tent, which I take pleasure in illustrating here (Figs. 11 and 12). As you see, it is composed of a steel frame, which can be folded together when not in use. Over this frame tight woven strong duck is stretched, so as to completely protect the patient against wind and sun. Into this half-tent the reclining-chair is placed in such a manner that the floor bracing, attached to the frame, is held down, and thus there is no danger of it being overturned, even if the wind is relatively strong. This protection can, however, also be procured at a much more reasonable rate by nailing together a few boards imitating the three walls and ceiling of the wicker basket or the half-tent. (In the home where there is ample veranda space such extra appliances become less necessary.)

When resting outdoors the patient should always be comfortably warm, and in winter he should be supplied with furs, and, if necessary, with a hot-water bag at the feet. The patient, when in the afebrile state, should take his regular walking and breathing exercises in the open air; the former, as well as the latter, should be regulated by the physician. They should never be left to the caprice of the patient. When there is fever there should be no exercise, and when the fever is high absolute rest in bed is essential. If moderately high, the patient may be allowed to alternate the rest in bed with the rest on the reclining-chair, but rest in bed as well as

Fig. 10

Fig. 10.—Typical sanatorium chair.

on the reclining-chair should always be in fresh, pure air.

Considering the walking and breathing exercises, I like to impress upon my patients the one fundamental rule, never exercise when tired and never to the extent of getting tired. To determine the distance the patient may walk, the thermometer in the hands of an observing physician is the best guide. Let the temperature be taken before and after the walk, and if experience tells that a half-hour's walk can be taken without a perceptible rise of temperature, but that an hour's walk is always followed by a rise of temperature of a degree or more, the physician will be able to regulate the prescription for walking with an almost absolute safety and certainty.

I consider breathing exercises a most valuable factor in the aerotherapy for phthisical patients. I have repeatedly published* these exercises, and I do not think it necessary to again describe them here in detail. I recommend them with certain modifications to all children and adults who breathe faultily; to the anæmic and those predisposed to consumption, and to the chronic tuberculous patients. As I said above, these exercises are never to be taken when the patient is tired, and I may add to this prescription, never after a hearty meal, never when uncomfortably or tightly dressed, never in an overheated room, or dusty or otherwise vitiated atmosphere. The purpose of these exercises is, of course, above all, to restore the faulty respiratory function, to facilitate hematosis, and indirectly facilitate expectoration and diminish cough.

Let me, however, in connection with breathing exercises, call your attention to the value of massage in developing the thoracic muscles. It is my rule never to inaugurate the breathing exercises with a patient until I have somewhat developed his usually much atrophied pectoral muscles by massage for a number of days.

For ambulant consumptives the pneumatic cabinet will also prove a valuable adjuvant in aerotherapy.*

Before leaving the subject of aerotherapy I feel that I must say a word or two on solartherapy. This adjuvant in the treatment of consumption has, I believe, not received sufficient consideration, and it is regrettable that in many well-equipped sanatoria so little attention is paid to the great advantage of a judicious exposure of the whole body in its nude state to the air and the rays of the sun at the same time. I speak from personal experience when I say I value most highly the carefully conducted solartherapy in the treatment of consumption. I confess that it is not always easy to find a suitable room for that purpose when treating patients in their homes, for neighboring windows are often near, and it will be necessary to use screens and other devices to assure the necessary privacy. In some instances, one may be able to build a special sun-room on top of a city house, in which case the treatment can be carried on with relative ease.

Let me rapidly give you here the directions for solartherapy: In winter the room should be heated to from 70° to 75° F. By and by the patient's skin will be less sensitive to the air, and the temperature of the room can be decreased. The room must always be well ventilated. In summer the upper parts of the windows can be left open.

As to the *modus operandi* of the baths, I recommend the following: The patient undresses entirely, but if he complains of cold feet he can keep his stockings or even his shoes on until he has become warm enough, and desires to take them off. He places first a warmed sheet around his body and then a large blanket; he then lies down on the floor in the sun, his head in the shade and slightly elevated by a cushion. As he begins to feel the warmth of the rays of the sun, he uncovers himself gradually until the whole of his body is exposed to the rays; he exposes his back by turning on his chest. He remains in the sun-room for from half an hour to two hours, according to the direction given him by his physician. He may change the recumbent to the sitting position or walk about. Like all the curative agents in the treatment of phthisis, the carrying out of this solartherapy should never be left to the caprice of the patient. Too much exposure to the hot rays may cause an erythema, an urticaria, or

*Knopf: Article on "Tuberculosis" in "Twentieth Century Practice of Medicine," Vol. 20, and Lecture on "Respiratory Exercises," *Johns Hopkins Hospital Bulletin*, Vol. XII, No. 126.

*Quimby: "The Pneumatic Cabinet in the Treatment of Pulmonary Phthisis, "*International Medical Magazine*, January, 1893.

Knopf: "Pulmonary Tuberculosis; Its Modern Prophylaxis, etc." P. Blakiston's Son & Co., Philadelphia, 1899.

other cutaneous troubles. To prevent these latter, I tell my patients to cover themselves with one or even two layers of the sheet when the sun's rays produce a slightly burning sensation. Should these cutaneous complications occur nevertheless, the sun-baths must be omitted for a time and the skin bathed in tepid water, and friction with lemon-juice applied. Headache, or a feeling of discomfort, is the signal to stop, no matter how short a time the bath has lasted. A high temperature is, of course, a contraindication to sun-baths. Such patients must remain in bed. Slightly feverish patients may be allowed to try solartherapy, but when experience shows that an elevation of temperature follows, the baths must be discontinued. While taking his sun-baths, the patient should perform frequent abdominal and thoracic breathing exercises.

We now come to hydrotherapy, which, to my mind, should play a most important part in home as well as in sanatorium treatment of consumption. Of course, it is essential that the skin and nervous system should be gradually accustomed to the use of cold water. This can be done first by dry friction, then by friction with alcohol, then friction with alcohol and water, and finally with water alone. While, as a rule, effective hydrotherapy can be employed in any home in which there is a bath-room and a faucet to which a hose can be applied, those of us who have experience in the practice among the poor know that in many of our tenement-houses a bath-room is still an unknown luxury. In such cases, as well as in those in which a visit to the bath-room is either inconvenient or not safe, I resort to the following simple method: A wooden chair is placed in a large, circular, English bathtub, and the patient sits astride the chair, holding the back with his hands and bending his head slightly forward. Then two, four, or more pitchers of cold or tempered water are rapidly poured over the shoulders. In cases in which the reaction is feeble the patient is quickly put back into his warm bed, even if not thoroughly dry.

The best time to take the hydrotherapeutic application is in the morning, half an hour or so after a very light breakfast. Patients accustomed to heavy breakfasts should take such after their douche and morning walk, but should take a glass

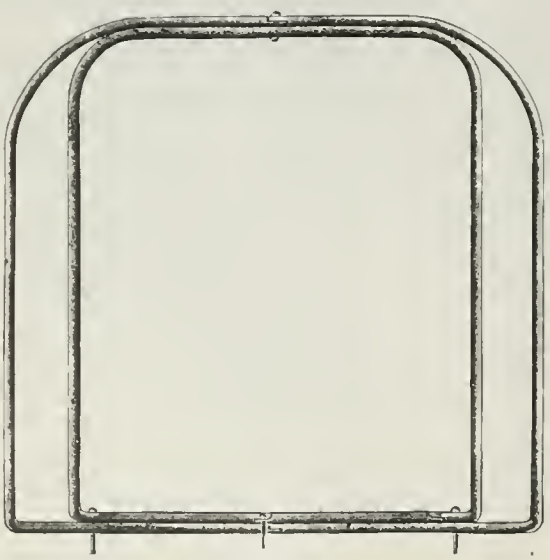

Fig. 12.

Fig. 12.—Steel frame for half-tent folded together.

of milk and a slice of buttered toast before leaving their room. A morning walk should, if possible, always precede the douche; this is for the purpose of creating what French hydrotherapeutists call a preaction.

Every douche or affusion should also be followed by a short walk or return to bed, according to the indication in the case. The cold douche should never last longer than twenty to twenty-five seconds, and one should always begin gradually, not giving

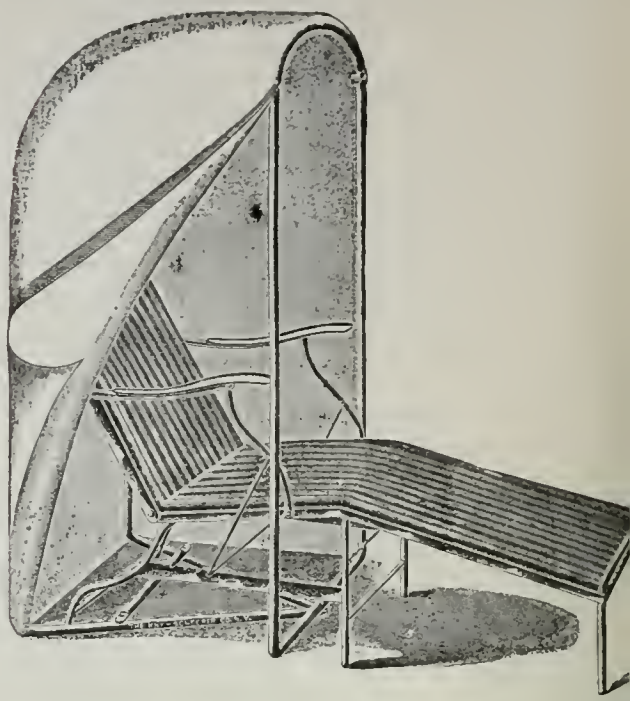

Fig. 11.

Fig. 11.—Half-tent for the rest-cure in the open air.

more than five seconds at first. The temperature may vary from 60° to 40° F. Only in exceptional cases would one need a more precise graduation of the temperature.

In patients above fifty years, it must be remembered that the usual reaction after a cold douche is slow to come, and in such cases it is best not to use the water too cold. A chilly sensation, continuing even after thorough drying and friction, should in all cases be a warning and a guide regarding temperature and duration of the douche. There are idiosyncrasies which must also be considered with some patients in regard to the application of a cold douche.

As stated already, I shall refrain in this paper from discussing in detail the various medicinal remedies used in the symptomatic treatment of phthisis pulmonalis, and I only desire to mention a few of the newer ones which have proved satisfactory in many cases. These are the creosotal—5 to 10 min. in hot milk—and the sodium cacodylate—$\frac{5}{6}$ of a grain—as rectal suppositories, as general tonics, the neutral camphorate of pyramidon—3 to 5 grains—as antipyretic, the agaricin—$\frac{1}{30}$ to $\frac{1}{15}$ of a grain—to control nightsweats, heroin—$\frac{1}{12}$ of a grain—for cough, suprarenal extract—3 to 5 grains—for hemorrhages, trional—5 to 15 grains—as hypnotic, and, lastly, hypodermoclysis, to combat the more serious symptoms arising from the secretions of the tubercle bacilli and their associates in the mixed infection.

I come now to the second portion of my paper. In the first I have endeavored to outline to you the sanatorium treatment at home, and the general practitioner will best know when he will be able to apply it. But I venture to say there is hardly a family practitioner who cannot recall cases in which his endeavors to institute a proper sanatorium treatment at the patient's home proved

utterly futile, and when he sincerely wished he could send his patient to a suitable institution in which he would receive proper care and supervision, and would have the best possible chance of a complete cure. The majority of cases in which the sanatorium treatment at home is impossible are among the poor. Those of us who are familiar with the unhygienic surroundings, the filth and dirt, the lack of light and air in many of the homes of the poor, in city and country, will know the utter hopelessness which confronts one when meeting a consumptive in such a home. In our own great city of New York where there is such an affluence of wealth and luxury you can find hundreds, nay thousands, of cases of consumptives in the various stages of the disease, living in the most densely crowded and unhygienic tenement districts without any medical attendance. I am the last to underestimate the splendid work done by our health department and its distinguished chiefs, Dr. Lederle and Professor Biggs, nor that of the newly-formed Committee for the Prevention of Tuberculosis of the Charity Organization Society, of which I am myself a member, in educating the masses as to the fundamental rules in the prevention of consumption; but the combat of tuberculosis, important as education is, cannot be accomplished by this one factor alone.

To know how to deal with the expectoration so as not to infect his fellowmen is, indeed, essential for every consumptive, but when handing to the consumptive a circular on the prevention of tuberculosis there is always the greatest care taken to inform him at the same time that his disease is curable, and it is but natural that the idea of cure should be as important to him as prevention.

But what chances of cure has he? When his chances are greatest, that is to say, in the early stages, when he is still up and about, attending to his work, he could not think of giving up work, for his family has to live; and should he have been even willing and able to go to an institution where he could pay a moderate price, he would not have found one. The few public and private purely philanthropical and semi-philanthropical hospitals or sanatoria within his reach are constantly filled. Of the 10,000 consumptive poor of this city who need institutional treatment we can hardly accommodate 800. How much longer shall our glorious city and State, known for their great charities toward all other unfortunate sufferers, distinguish themselves so sadly by their indifference toward the consumptive poor? If there is any class of sufferers deserving our greatest sympathy, and which, on account of the very nature of the disease, are often shunned, and because of the chronic character of the disease well-nigh always in financial distress, it is the consumptives.

Private and official phthisiophobia is still flourishing. We hear from California of renewed attempts to exclude consumptives, and daily do we meet with people who have a horror of the presence of a consumptive, no matter how careful he may be with his expectoration. Yet the clean consumptive is as safe an individual to associate with as any other person. In many States of the Union there is now a strong awakening to establish sanatoria, but from the reports which have reached me nearly all have difficulty in finding suitable localities because of the neighbors objecting. I have so often said and demonstrated through reliable statistics that in Goerbersdorf and Falkenstein, where five of the most flourishing sanatoria for consumptives have now been in operation for thirty and forty years respectively, the mortality from tuberculosis among the villagers has actually decreased to one-third of what it was before the establishment of the sanatoria.* This reduction in the mortality from consumption has doubtlessly been due to the sanitary habits which the inmates of the sanatoria practise and the villagers imitate.

There is not the slightest reason why our own and every other city in the United States should not have, after the example of Germany and France, enough sanatorium facilities, at least for its own consumptive poor, where the curable can be cured and the hopelessly ill be made comfortable and prevented from creating foci of infection for their own kin and neighbors. We need local State and municipal sanatoria and sanatoria created and maintained by private charity. What has already been done by States and municipalities we highly appreciate, but it is so little compared with the needs that it resembles a drop of relief in an ocean of woe. My perhaps somewhat extensive experience with the various sanatorium movements in this State and others has taught me the one thing, that whatever relief may come concerning not only the medical but also the social solution of the tuberculosis problem must come from within our own ranks.

I ask you, my fellow practitioners, and particularly those of you who have influence with the rich and mighty, to make your influence felt and appeal to them to do their duty. Describe to them the sufferings of body and soul of the honest consumptive laborer, the woman or child who must suffer and die, not because their disease is incurable, but because there is no place to cure it. Tell your philanthropic friends that, notwithstanding the statement recently made by Professor Robin of Paris that tuberculosis once established is not curable, physicians in his own country and everywhere in the civilized world cure and have cured, and lastingly cured, consumptive patients, though the disease had established itself in their system beyond a shadow of doubt. Tell them that these patients were treated and cured by the very sanatorium method which this French savant so much depreciates.

Convince them that although we have not yet found a specific for the treatment of consumption, vast advances have been made in the preventive and curative treatment of the disease during the last twenty years, and our own country has had its good share in this progress of modern phthisiotherapeutics. The results in the sanatorium treatment, thanks to a more thorough clinical knowledge and better understanding of aero- and hydrotherapy and the dietetic treatment, have shown a steady gain in the percentage of cures.

Thus, if another American philanthropist should wish to donate $7,000,000, like the generous-hearted Mr. Rockefeller, to search for a specific to cure consumption, ask him to be allowed to use the greater portion of these millions for the purchase of the worst tenements in your city and the erection of model homes for the laborer in their stead; for the establishment of a few playgrounds, for public baths, and last but not least for the establishment and maintenance of sanatoria for poor and moderately poor consumptives. You can assume the responsibility of telling the generous wealthy men and women who wish to help their suffering fellowmen the true situation, namely that $7,000,000 rightly used with our present knowledge of the prevention and cure of the disease, we could attain

*S. A. Knopf: "Tuberculosis as a Disease of the Masses and How to Combat It." International Prize Essay. M. Firestack, publisher, 110 West Ninety-sixth street, N. Y.

results to equal those that may be expected from the specific remedy yet to be discovered.

To the statesman say that every life lost from consumption represents an annual economic loss of $850; tell him that every badly ventilated workshop or tenement constitutes a danger to the public health. Ask him to enact such laws whereby ample ventilation and light shall be forever secured in public and private dwellings. There are in Manhattan over 200,000 and in Brooklyn over 125,000 dark, interior rooms without a window of any kind and having no means of light and ventilation. Such attempts as are now before our New York Legislature to cripple the work of the Tenement-house Commission and allow greedy contractors to erect tenements without light and air, veritable breeding places of consumption, should receive the just condemnation of every citizen in the land.

Tell the municipal legislator that every consumptive cured in the early stages (and 75 to 85 per cent. can be cured) will never become a burden to the community, which, when poor, he will invariably become, and that he will then cost a great deal more than six or eight months' sojourn in a sanatorium at a dollar a day. Tell your city fathers, who are always willing to listen to a just cause, that there are in nearly all our large centers of population not only hundreds, and sometimes thousands of poor consumptives without care and treatment in unhygienic homes, but that there are many consumptives without means wandering about these cities who are actually homeless. That I may not appear to you simply an alarmist, let me quote some facts concerning our own metropolis. Through the courtesy of my esteemed teacher and friend, Prof. Hermann M. Biggs, the Health Officer of this city, I have come in possession of the following statistics:

There have been in the Borough of Manhattan during the year 1902:

950 cases of tuberculosis that have died in hospitals and found to be "not known" at address given;
456 cases where no address was given;
275 cases where address given was a lodging-house; and
106 cases where address given was outside Borough of Manhattan.

1,787 cases in all.

Following is a list of hospitals in which these 1,787 homeless tuberculous cases have died:

354 at Metropolitan Hospital.
279 at Bellevue Hospital.
271 at St. Joseph's Hospital.
168 at City Hospital.
143 at Almshouse Hospital.
92 at Manhattan State Hospital.
78 at Seton Hospital.
72 at St. Luke's Hospital.
40 at Loomis Hospital.
35 at Workhouse Hospital.
32 at Lincoln Hospital.
30 at Montefiore Home and Hospital.
23 at Gouverneur Hospital.
17 at St. Vincent's Hospital.
13 at Foundling Hospital.
12 at House of Relief Hospital.
97 at various hospitals where the number of deaths was less than ten.
31 found dead in lodging-houses, hallways and other places.

1,787 cases in all.

Convince those in power that while the consumptive poor without treatment at home constitute a source of infection to their own kin and neighbors, the homeless consumptive, wandering about the city, doing odd jobs here and there, sleeping one night in a lodging-house and the next in a hallway, constitutes a source of infection far greater than a patient confined to one or two rooms. It is the homeless consumptive who spreads the disease everywhere he goes by disseminating his countless bacilli through indiscriminate expectoration.

In view of the facts presented, are you not justified in telling your philanthropic friends that we now have enough libraries, universities, colleges, churches, and even general hospitals, but that there is an urgent and crying need for local sanatoria for the consumptive poor adults, that is to say, institutions situated near our large centers of population. Plead for the establishment and maintenance of such sanatoria with all your eloquence and earnestness. Plead for agricultural colonies where to send the cured consumptive.* Plead also for seaside sanatoria for tuberculous and scrofulous children, and incidentally plead for better, brighter, and healthier homes for the poor. Make your influence felt with the sanitary authorities to improve the hygiene in workshops, factories, stores, etc. With the hygienic improvement of the home and the workshop of the laborer we will strike effectively at one of the principal causes of the spread of consumption. Persuade the people who still believe that climate alone can cure consumption that it is in reality only a secondary factor, and that excellent results can be obtained in well-conducted sanatoria in our own home climates. Tell them that the majority of the consumptive sufferers are among the laboring classes, and that it is a social and economic advantage to cure these people in the same, or nearly the same, climate in which they will have to live and labor after their restoration to health. You can even tell them that such cures obtained in our home climate are, as a rule, even more certain and more lasting than those obtained in more congenial climes.

With a few more gifts such as recently bestowed by Mr. Henry Phipps† and Mr. Charles M. Schwab,†† with ample facilities in all our States and cities for the treatment of the consumptive poor and those of moderate means, a general education as to the means of the prevention of the disease, a better housing of our laboring classes, and a judicious general improvement of their social conditions, there is no reason why our beloved America should not be the first land in the world to eradicate the great white plague forever.

*Knopf, S. A.; "A Plea for Homes for the Convalescent Poor." *New York Medical Journal*, November 1, 1902.

†Mr. Henry Phipps of New York recently gave $1,000,000 to establish in Philadelphia an institution for the study, prevention, and treatment of tuberculosis. The institution, which will be named "The Henry Phipps Institute," will be entirely independent of charity. Dr. Lawrence F. Flick of Philadelphia will be the director.

††Last year Mr. Schwab purchased sixty-five acres of land and lake on the Staten Island shore. This property is being turned into a great park playground for the children of New York. There will be facilities for bathing, nature study, play on the beach, and all sorts of outside sport. The institution is to take one thousand children every day during the summer months to this park. The total cost of the plant will reach nearly $1,000,000 and the operating expenses about $100,000 annually.

16 West Ninety-Fifth Street.

The Homeopathic Medical Society of the State of New York held its annual meeting in Albany last week. The election of officers resulted as follows: *President*, Dr. J. N. Le Seur, Batavia; *first vice-president*, Dr. E. Rodney Fiske, Brooklyn; *second vice-president*, Dr. Joseph T. Cook, Buffalo; *third vice-president*, Dr. C. A. Ward, Binghamton; *secretary*, Dr. D. G. Wilcox, Buffalo; *treasurer*, Dr. Charles F. Haines, Utica.

THE PRESENT STATUS OF SURGERY OF THE GALL-BLADDER AND BILE-DUCTS.*

By WILLIAM J. MAYO, A.M., M.D.,
SURGEON TO ST. MARY'S HOSPITAL OF ROCHESTER, MINN.

THE medical profession has been somewhat slow to accept the modern view of gallstone disease, and, although introduced at about the same time as the "appendicitis problem," it is far from as definite a solution. The reasons for this are apparent, and based upon fairly reliable grounds. The patient is usually along in years, and often, by reason of degenerative lesions or adipose tissue, not a good subject for operation, and, again, death does not often come with that tragic suddenness which ofttimes characterizes appendicitis. But all of these considerations are of minor importance when compared to the major obstacle to a proper understanding of this common malady, which is by no means the innocent disease our predecessors taught us to believe. It is the "slumbering gallstone" which stands in the way. Riedel estimates that 2,000,000 Germans have gallstones, and of these only 100,000 have symptoms. Kehr states that 10 per cent. of adults have gallstones, and only 5 per cent. of these have trouble resulting therefrom. Bevan found that 16 per cent. of the cadavers at the Rush dissecting rooms had gallstones, but he also called attention to the significant fact that the material was drawn from almshouses and charity institutions. Bevan says, "this does not fairly show the true percentage, because, as a class, these cadavers represent the people who have seen the hardest side of life." This comment is just, and applies equally to all of the collected statistics, as, almost without exception, they are drawn from large hospitals and similar institutions. This very fact indicates that the patients must have been in a condition in which the two cardinal factors in gallstone formation were most likely to be present: defective circulation of bile, and that mild infection aptly termed "stone-building catarrh."

It is altogether probable that the accepted percentage, as applied to the public at large, is too high; yet even if 5 per cent. of adults have gallstones and 95 per cent. of these peacefully "slumber," it makes the physician pause before recommending an operation. The chance of picking out the surgical case would be but one in twenty. This is not the fact, for if the calculi are really latent, one does not know of their presence unless discovered during a surgical operation for some other purpose.

The removal of slumbering gallstones under such circumstances can be compared to normal appendectomy. I do not wish to be understood as not advising the removal of latent calculi on such occasions, provided it does not seriously add to the general operative risk, especially as intelligent examination of the patient's history will often develop certain stomach symptoms which were due to this cause, and from which relief is thereby obtained. We have grown so accustomed to looking upon the colic as the one symptom of gallstones that we often, if not usually, overlook its more chronic manifestations.

The proportion of actually "slumbering" gallstones is much less than we have heretofore thought, and in a considerable number of cases the term is a relative one, and means that the disturbance is so slight that the cause is unsuspected.

This brings us to the question—what causes latent calculi to become active? There are two explanations: one that of Kehr, which lays everything to an infection, and the more generally adopted theory of mechanical interference with drainage from the gall-bladder. As a matter of fact both causes are usually present, the one depending upon the other. If the circulation of bile is free, the germs will be mechanically washed away, so that lack of drainage is a most important element. On the other hand, infection acts as an irritant to the gall-bladder, and generally induces the contractions which engage the stone at the entrance of the cystic duct. In other cases the swelling of the gall-bladder and ducts from the infection causes,of itself, mechanical obstruction. The resulting disturbance depends upon the acuteness of the infection, and upon the ability of the organ to distend. The gall-bladder, in this respect, has the advantage over the appendix, as well as a far better blood supply. Rupture and gangrene are therefore rare, and sudden death from fatal perforation does not often occur. The appendix and gall-bladder are both dependent organs with a limited outlet, and liable to stone formation, but the grade of infection in the gall-bladder is usually mild in character, while its distensibility equalizes the tension, which is so fatal a factor in the appendix, containing, as it does, the most virulent of bacteria.

The infection in the gall-bladder may die out, especially colon infections, but this is not to be expected. Normal bile is free from microorganisms, as shown by Netter and Naunyn. Mieczkowski, in fifteen cases, aspirated bile from a normal gall-bladder during laparotomy for other purpose, and all were sterile. Fraenkel, Krause, and others found normal bile to be a poor culture medium, but thick, stagnant bile a fairly good one. Bacteria may remain in an attenuated condition a long time in the gall-bladder, but, as proved by Miquot and Miyoke, capable of return to virulence under favorable circumstances.

The calculus gall-bladder was found by Mikulicz to contain bacteria in eighteen out of twenty-three cases, and numerous observers have confirmed these results. We may take it for granted that all cases of slumbering gallstones contain bacteria encapsulated, perhaps, like in an old osteomyelitis, yet needing but some interference with drainage to start into activity. Or reinfection from the intestine may occur, either directly or by way of the portal circulation and bile itself.

Under favorable circumstances troublesome gallstones may again *rest*, and the various medicinal springs which have obtained a reputation in the treatment of biliary calculus probably act by keeping up that free circulation of bile which is so essential to the well-being of the host. The *active* gallstone, as long as it has periods of latency, is debatable ground, and can be claimed by either the internist or the surgeon. It is the case of chronic and relapsing appendicitis over again. The age and general condition of the patient will, however, be a more dominant factor in this class of cases than in disease of the appendix. The question for consideration is whether, in view of the possibility, nay, probability, of further extention of the trouble, it is not wise to remove *active* gallstones early. The results of early operation for gallstone disease are remarkably good. Up to December 11, 1902, we had about 250 cases of this kind out of a total of 454 operations, with a death rate of less than 1 per cent. Robson, Kehr, Ochsner, Murphy, Richardson, and practically all of large experience give statistics which tell the same story. In over 2,000 operations of this kind, in the hands of six surgeons, there was not a single instance of reformation of the gallstones. In this field of surgery delay breeds misfortune.

Complications are due to changes in the wall of the

*Read by invitation before the Academy of Medicine, New York, December 18, 1902.

gall-bladder or involvement of the bile-ducts, and the calculi may then become but an incident in the pathological process which they initiated. Repeated infections with prolonged interference with drainage cause the walls of the viscus to become infiltrated with inflammatory products, and the connective tissue formed interferes with its elasticity under pressure, and limits its power of contraction. This introduces the element of *tension*, and results in more marked symptoms, as pointed out by Berg. The struggle is now to a finish, and either the obstructing stone is forced through the cystic duct into the common duct, there to remain, or pass out into the intestine, or it may become encysted in a thick-walled pouch composed of the remains of the gall-bladder, causing recurring attacks of inflammation. The variety of changes found in the gall-bladder remind one of a chronic appendicitis, in which deformed and partially obliterated forms with stones encapsulated ofttimes in the surrounding tissues are not uncommon. Adhesions to surrounding viscera may prevent fatal perforation, or divert it into a neighboring viscus with spontaneous discharge of the infected fluid, and, incidentally, of the calculi. Even if all the stones are so discharged, which by no means often happens, the adhesions remaining may be a prolonged source of distress to the patient. An operation in this stage is fraught with some danger, and the gall-bladder can no longer be expected to return to the normal. It may do so, but in a number of cases interference with drainage, due to some permanent change in the cystic duct, gives rise to future colics or pain.

It is in this class of cases that cancer of the gall-bladder is most liable to supervene. In 454 operated cases, we found cancer of the gall-bladder or bile ducts in twenty-one cases (5 per cent.), and in nearly all a distinct history of previous colics was elicited. All of the cases in which the gall-bladder was examined contained stones. The chronic irritation of calculi in a gall-bladder in which inflammatory changes have taken place seems to be the usual precancerous condition. This is certainly a serious factor in deciding as to operation, a one-to-twenty chance is not lightly to be risked.

The possibility that all of the stones may be expelled through the ducts is alluring to both the physician and the patient. This may happen but we have never operated upon a case in which the patient brought us stones detected in the fæces, that the gall-bladder did not contain more.

In forty-nine of our cases stones were found in the common and hepatic ducts with or without jaundice; but in any event necessitating a most serious operation. Robson found stones lodged in the common duct in 20 per cent. of his cases. Evidence that a stone has successfully passed into the intestine does not contraindicate operation; it is altogether probable that more stones remain, and the next *labor* may end prematurely, leaving one or more stones in the duct. Occasionally one finds a case in which such stones have remained for years in the common or hepatic ducts, with comparatively little trouble; but such instances are rare, and the rule is that infection of the liver ducts, and occasionally those of the pancreas, render surgical intervention a necessity, and, with the jaundice which usually coexists, the operation is far from safe.

Infection of the liver ducts introduces an element of uncertainty in the prognosis, and to this cause the majority of deaths after operation may be traced. In these cases the condition described by Eisendrath as "hepatargia," or cessation of liver function from degeneration of the liver parenchyma, may be present. Quincke found that cholangitis, secondary to colon infection of the gall-bladder, was more liable to cause acute liver degeneration than when due to the ordinary pus microorganisms, although this bacillus has a shorter life history. Talma demonstrated that either colon or typhoid bacilli injected into the gall-bladder would not infrequently travel up the hepatic ducts and cause extensive pathological changes in the liver. Lavastine recently reported six autopsies in cases of acute liver insufficiency in which these changes were most marked. In our experience this has been the cause of death in nearly one-half of the cases. The symptoms of this condition are chiefly nervous, and usually sudden in onset and rapid in their course. The only safeguard in operation upon cases with infective cholangitis is free drainage of the bile to the surface.

In 1897 we operated upon two cases in which the diagnosis of gallstones seemed certain, and in neither case were calculi found. The gall-bladder was not opened, although its walls were thickened and lacked that peculiar bluish green color characteristic of it when filled normally with bile. The operation was thought to be a mistake in diagnosis. About this time we had several cases in which we could not be sure whether the unopened gall-bladder contained calculi or not. In two instances it was incised; no stones were found, but thick mucus and bile. They were cured by drainage. During the next two years we had a small number of such cases, and finally reoperated upon the two original patients, in whom the symptoms had been continued, and obtained a cure in each by this means.

In 454 cases we have had twenty-six of this description, evidently a chronic cholecystitis without stones, but with a similar symptomatology; the colics were undoubtedly due to plugging of the bile passages with the tarry material with which the gall-bladder is ordinarily found filled. In nearly all of these cases we have, before opening and draining the gall-bladder, carefully examined the pylorus, the appendix and the right kidney to complete a differential diagnosis. In all of the cases the gall-bladder was evidently the affected organ, its walls being thickened and very often exceedingly adherent to neighboring structures. There was no evidence that stones had ever been present.

I have recently written to each of these patients to find out the present condition, and from the twenty-three letters received nineteen replies; of these fifteen write that they are well, two improved, and two unimproved. Three died as a result of the operation, from hepatargia. This death rate alone demonstrates that the infection is often more active than in gallstone disease.

A few words in regard to the principles underlying operations upon the gall-bladder and bile ducts. The most important question is that of infection, and as to whether it is acute or chronic, and especially whether or not it involves the liver ducts.

Every gall-bladder containing calculi can be looked upon as infected, although, with the free circulation of bile and nearly normal gall-bladder found in slumbering stones, it is slight, and the "ideal" operation—that is, complete closure of the gall-bladder and abdominal incision—may be performed; but it will occasionally, even then, lead to disaster—to say nothing of the danger of overlooking stones—which may and does happen to the most expert. The ideal operation has been performed largely upon these latent cases, found during other operations, and the surgical conclusions drawn cannot be safely applied to gallstones in a state of activity, which o

itself argues an infection of a more acute type. Cholecystotomy and drainage is the operation of choice in these cases. Patients suffering from active gallstones with periods of latency, in a fairly normal gall-bladder with patent ducts, are nearly always cured by this method. Drainage is continued until the bile is normal. This is a very safe operation, and, as the gall-bladder is fastened to the abdominal incision, the fundus is permanently elevated and gravity drainage through the cystic duct is even better than in the normal state. Gall-bladders with thickened walls, and especially if the cystic duct has been obstructed, are liable to give trouble after cholecystotomy, and, if possible, the organ should be removed. If the liver ducts are entirely free from involvement, then, and only then, should the cystic duct be tied and the gall-bladder excised without drainage of the bile from the liver ducts; but if the hepatic ducts are involved, free drainage of the bile to the surface must be provided for by leaving the cystic duct open. Kehr says that the hepatic ducts require drainage in 37 per cent. of cases, and, with increased experience, we believe that this is not too high a percentage.

It was in the management of such cases that we recommended the removal of the mucous membrane, the peritoneal, and as much as may be of the muscular coats being left. The cystic duct is cut across and left open in the bottom of the pouch, the outer margins of which are brought to the surface and drained in the same manner as after cholecystotomy. It gives all the advantage of temporary hepatic drainage with the permanent benefits of cholecystectomy. To cut the gall-bladder away, leaving the cystic duct open, spouting bile into the abdominal cavity, requires a quantity of drainage, and does not compare in ease and safety with the method we have described and practised. The mucous membrane of the fundus of the gall-bladder does not separate easily, but in the vicinity of the cystic duct it can be readily removed. For this reason we usually amputate the fundus and remove the mucous membrane from the lower portion. We can recommend this with much confidence, as in a considerable experience we had no deaths and no relapses. A recent writer in the *Annals of Surgery* condemns the operation on purely theoretical grounds, in which he misses the vital point of drainage from the open cystic duct, and states that I ligate the cystic duct. This is exactly what I do *not* do. In stones in the common duct, drainage of the hepatic duct is essential. This usually has been done by suturing the common duct and draining through the gall-bladder by cholecystotomy.

W. E. B. Davis first recommended leaving the common duct open after removing stones, for drainage of the hepatic ducts, and as these cases are usually jaundiced and bad subjects for operation, this time-saving practice has often proved to be of the greatest value.

In forty-nine choledochotomies we had but two deaths, and the method of Davis, in whole or part, has been the one of choice, the gall-bladder being also drained at the same time. In comparing the surgery of the gall-bladder with that of the appendix, this essential point of difference exists: in removing the appendix, every effort is made to prevent leakage from its attachment to the cæcum, while in the gall-bladder, the necessity of thorough drainage from the liver ducts out of the external incision is, in many cases, necessary to success. Of the 454 cases, up to December 11, 1902, upon which this paper is based, 438 are from the records of St. Mary's Hospital of Rochester, Minn., and sixteen occurred in the Minnesota State Hospitals for the Insane.

The operations were performed by my brother, Dr. Chas. H. Mayo, or myself.

POST-OPERATIVE MALARIA, WITH A REPORT OF TWO CASES.*

By JOHN T. MOORE, M.D.,
TEXAS.
ASSOCIATE IN CLINICAL MEDICINE, UNIVERSITY OF TEXAS, MEDICAL DEPARTMENT, GALVESTON.

THERE is a common idea among surgeons who live in malarial districts that there is apt to be an outbreak of malarial fever following a severe injury or an operation. Such an idea is so prevalent that oftentimes antimalarial treatment is given as a part of the preparatory treatment.

While these views are no doubt correct, yet they are not founded upon other than clinical observation, for but few observations have been made of a positive character to determine whether these cases had present a malarial infection previous to the operation. Blood examinations are not often made even when there is an elevation of temperature following operative procedures. The rise in temperature is accounted for in various ways as due to the operation, or else quinine is given as a therapeutic test to exclude malaria.

Malarial fever manifests itself in so many ways that it is not an easy matter to make a diagnosis that is at all positive without a careful blood examination by one who has had sufficient training in this character of work to be able to say whether the parasites are present or not. I know of no field where microscopic training is of greater value.

I appreciate that men have treated and diagnosed malarial conditions long before the hæmatozoon was discovered, but alas, how many ailments are unjustly called a "touch of malaria!" The expression is too often used, and many times it only shows that the case has not been diagnosed. I know too, that it is commonly taught that any temperature that resists the action of quinine is not malarial. So great an authority as Osler ("Practice of Medicine," fourth edition) says: "If the practitioner will take to heart the lesson that an intermittent fever which resists quinine is not malarial, he will avoid many errors in diagnosis." In the main this may be correct, but there are many cases to which this cannot apply. Cases vary very much in the time required and the dosage necessary to destroy a sufficient number of the parasites present in order to prevent a rise of the temperature above normal.

Thayer ("Lectures on Malarial Fevers") says of quinine as a therapeutic test: "No malarial fever which we now know resists large doses of quinine for more than three or four days. It is quite safe to say that if the process be malaria the temperature will be quite normal, or at least will have shown a marked break by the fourth day, usually earlier. If quinine fail to influence the fever, we may rest assured that the process is either nonmalarial or else that a complication exists."

This course is probably the best that could be adopted by the doctor who has no other means of excluding malarial fever. We meet cases now and then that resist the action of quinine longer than the above-mentioned period, not showing the least effect of the quinine. I had a case under my care last summer who took from thirty to forty grains of quinine for more than ten days without any appreci-

*Read before the South Texas Medical Association, at Houston, Texas.

able effect upon the temperature or upon the parasites. The quinine was given in solution and was not vomited. Then again, we have a class of cases that have a normal temperature and yet the parasites can be demonstrated in the blood. These cases need to have quinine administered to them to prevent the paroxysms which are almost sure to come unless they receive treatment.

It is to this latter class of cases that I wish especially to direct attention. These cases when operated upon are almost sure to suffer a relapse. It was a common thing during our investigations last summer to find the parasites of æstivo-autumnal fever present in the blood of malarial cases many days after the temperature had reached the normal, and the patient still taking quinine. Now by this therapeutical test one could never say how long to continue the quinine in any case of fever, and consequently oftentimes the quinine would be withheld after the temperature had reached the normal with the parasites still present in the blood in sufficient numbers to cause a relapse as soon as the vitality of the patient is slightly lowered by some injury or by some surgical procedure.

This matter of the latency of malaria in connection with surgical cases is a very interesting and important one. No one would think of operating during a known malarial infection unless in an emergency, yet I do not doubt that operations are done with fatal result in cases that might have been saved, or at least would not have suffered mutilation, had the malarial infection been recognized and thoroughly treated.

Welch, in Loomis and Thompson's "System of Medicine," says that during the first seven years of the Johns Hopkins Hospital not a case of post-operative or postpartum malaria was seen. He does not deny that cases of post-operative malaria do occur, but thinks that most of the cases diagnosed such without the microscope were due to sepsis. He refuses to accept a diagnosis other than by the microscope in these cases.

Case I.—Mrs. W. B. P., aged thirty-four years; came from Rosenberg, Tex., near the Brazos river, and a very malarious locality. She had chills and fever every Fall since living there. She came to Galveston about October 1, 1900. Soon after coming here she consulted me for a severe attack of dysentery. Numerous amœba were found in the stools. No note of a blood examination was made in my history of the case, but as I have been in the habit of making routine blood examinations in such cases, I feel sure that one must have been made. She was treated for this dysentery for about ten days and improved so much that she returned to Rosenberg apparently cured. During November and December she suffered from pains in different parts of the body and felt very nervous.

On January 17, 1901, she had a distinct chill, followed by a fever and sweat. She was given large doses of quinine. Had three more third-day chills, but after this she had no other chills, though she still felt extremely nervous, suffered more or less pain, and had a very poor appetite. Her complexion became exceedingly sallow and she lost considerable weight.

She returned to Galveston on April 7. I was consulted again on April 10. There was no history of chills or fever since January, while at Rosenberg. Said she had tingling sensations in the limbs and was extremely nervous and irritable. She had a poor appetite and complained of loss of energy. Pain in the lower part of abdomen. Menstruation regular, but painful. Was suffering from a slight leucorrhœa.

Examination showed a laceration of the perineum, a double tear of the cervix, and considerable prolapse of the uterus. The uterus was large and tender. The temperature normal. Reflexes normal, except the patellar reflex was slightly increased.

On May 6 chloroform was given, the uterus curetted, and the cervix repaired. Her improvement was very rapid. Three weeks later, under chloroform anæsthesia, the perineum was repaired. She seemed to recover very slowly after this operation. There was no suppuration from any of the stitches, but the temperature refused to go below 99° F.

I removed the stitches on the twelfth day. Temperature was normal. Result of the operation excellent. The nervous trouble she had complained of so much seemed to have entirely disappeared.

On June 30 I was again consulted for a burning sensation of the skin and pain in the joints throughout the body. As these were the symptoms that she complained of previous to the operation, I naturally became fearful that she was not going to be relieved so promptly as at first thought after doing the operations.

On July 3 I found she had a temperature of 101.5° F. She had had no chill or chilliness, and expressed surprise when I told her that she had fever. I made a careful examination, but could find nothing to account for the fever. I decided to make a blood examination, and found two groups of the tertian parasite present. I now gave her full doses of quinine, with complete relief of all the troubles of which she complained.

Her husband writes me that she is now entirely well, and as a further evidence of her good health she has presented her husband with another fine boy. It is now more than a year since she was under treatment and her health is perfect. (August 9, 1902.)

Case II.—Mrs. O. B.,* aged twenty-six years. She was admitted to the John Sealy Hospital under the care of Dr. J. H. Ruhl, September 6, 1901. Has resided in Galveston for six years, except during a part of July, which she spent in Beaumont, Tex., a very malarious district. She had typhoid fever at the age of fourteen. Since this she has been a strong, healthy girl. Menstruation begun at the age of fourteen. Normal. Was married at sixteen. One child at seventeen, and another when twenty years of age. Menstruation has been irregular and painful since the birth of last child. Severe pain in the back and both iliac regions. She has had no chill or fever since the latter part of July, 1901. She has complained of aching all over for more than a month. Her appetite is poor, feels drowsy, and has no energy.

On September 7, Dr. Ruhl, to whom I am indebted for the opportunity to present this case, operated, removing a pus tube and one ovary. Patient did well. The temperature remained normal until about the fifth day after the operation, when a slight rise in the temperature was observed. There was no evidence of suppuration that could be detected.

I made a blood examination on the 15th and found æstivo-autumnal ring forms of the malarial parasite. There was no leucocytosis.

On September 16 I again examined the blood and found many crescents and ring forms of the parasite of malarial fever. No leucocytosis present. Quinine and iron were given, and I am told by Dr. Ruhl that a perfect recovery has resulted.

Russell (*Johns Hopkins Hospital Bulletin*, November-December, 1896) reports four very interesting cases of post-operative malaria, under the title

*This case was referred to in *Journal of Tropical Medicine*, March 15, 1902, "Duration of Latency of Malarial Fever," etc.

"Malarial Infection as a Source of Error in Surgical Diagnosis." Had I the space I would present a synopsis of these cases. They are well worth studying.

Thayer ("Lectures on Malarial Fevers," page 207) reports a case of post-operative malarial fever following the removal of a cancerous tongue. The malaria was of a pernicious type.

Bell and Stewart (*Journal of Tropical Medicine*, September 2, 1901) present their findings in the study of about 400 cases of various diseases that came for treatment. Their observations are most valuable, showing the frequent association of malaria with other diseases.

Of two cases of liver abscess treated, both had malarial parasites in the blood. Two cases of appendicitis were treated, and they both had the parasites present. One of these cases developed appendicitis after the diagnosis of malaria had been made. Four abscess cases all contained the parasites of malaria in their blood. Of nine cases of shock from injury, five showed malaria present.

My studies and reading lead me to make the following observations:

1. A blood examination by the microscope should be made of every case from a malarial locality before operation. All of Texas may be regarded as malaious to a more or less degree. I am convinced by my studies of the latency of malaria that many infections that have lain dormant for weeks, and even for years, may be rekindled, and become not only a complicating factor, but may throw the balance against the patient and result in his death.

I am also of the opinion that many cases are operated on in malarial localities that could have been cured by recognizing the presence of the parasites and giving antimalarial treatment. Russell (*Johns Hopkins Bulletin*, 1896) speaks of an instance of this kind in the following words: "A patient presented herself to a surgeon complaining of pain in the lower abdomen, pelvis, and back, with chills and fever. Upon examination a mild pelvic peritonitis was found. She was advised to have the tubes and ovaries removed, and submitted to the operation. The patient had a severe chill next day, followed by a rise of the temperature to 107° F. and collapse. The blood was examined and found teeming with malarial organisms." The operation was wholly unnecessary.

I feel sure that there have been many instances in which a careful blood examination before an operation would have saved the sacrifice of the pelvic organs of the cases thought to be due entirely to diseases of the uterus, tubes, or ovaries.

2. Malarial fever is often aroused from latency to activity by some injury or surgical operation. It is here that a blood examination will not only enable one to save his patient oftentimes, but it will also relieve the strain of wearing out doubts as to the cause of a chill and high fever without having to make a therapeutical test, which at best is uncertain. Both of the cases here reported are good examples of this group of cases.

In case number one the nervous symptoms were the most prominent, and I thought them due entirely to the lacerated cervix, torn perineum, and endometritis. While all the operations I did were indicated and apparently gave relief, yet when the malarial infection was rekindled they returned and promptly again disappeared under the administration of quinine.

In case number two it would be very interesting to know what the malarial infection had to do with the pus tube; probably nothing, but in cases of this sort I think one endangers the life of the patient materially by operating at a time when the malarial parasite is present. Cases that are malarial that are not too urgent should wait until malarial treatment is given. Although this case had had a normal temperature for ten days previous to the operation, I feel sure that the microscope would have revealed the parasites.

3. Malarial fever, especially the chronic forms, bring about a most unfavorable condition for the healing of wounds and the reaction from the shock of the anæsthesia and operation. This is recognized by both the old and the modern writers on medicine and surgery. Verneuil ("International Encyclopedia of Surgery") emphasizes the above. He says: "It is especially in cases of malarial cachexia that are observed that slowness and insufficiency of repair which terminate in serious diffuse inflammations, or even in gangrene, and which are not always subdued by antiperiodic remedies."

Osler reports a case of multiple gangrene due to malaria (*Johns Hopkins Bulletin*, February, 1900).

McElroy also reports a case of malarial gangrene (*Journal of the American Medical Association*, September 14, 1901).

Marchiafava and Bignami ("Twentieth Century Practice of Medicine") say: "Chronic malaria may react upon the wound, causing difficulty in the process of cicatrization, and facilitating the pyogenous infection."

Is it not reasonable to suppose that some of the fatal cases of operation are due to the presence of the malarial parasite?

I wish to say, in conclusion, that those of us living in malarial districts have a rare opportunity for settling many of these problems by making careful and systematic blood examinations of all of our cases before and after operation.

TRACHOMA IN THE PUBLIC SCHOOLS OF NEW YORK.*

By WALTER EYRE LAMBERT, M.D.,
NEW YORK.
SURGEON, NEW YORK EYE AND EAR INFIRMARY.

Most of you are aware, no doubt, of the enormous increase in the number of cases of trachoma which have presented themselves for treatment at the various eye clinics in this city during the past few months, and probably you have read in the daily papers of the prevalence of this disease in the public schools of the city.

On account of the widespread interest in this condition of affairs, not only to the profession but to the public at large, it seemed a fitting time to bring the subject up for discussion before this society.

In the preceding papers the subject has been presented from a purely scientific point of view. It has been assigned to me to inform you somewhat of the conditions which exist in the public schools of New York; to tell you what has been done, and to suggest for discussion how it would seem best to meet this real evil.

It would seem well, as a preliminary, to recall the condition of affairs that existed some years ago in the various residential institutions in New York, and the great benefits which have been brought about by intelligently dealing with the matter.

As far back as 1885, Dr. Derby, in a paper read before the Academy of Medicine, on the subject of "Contagious Ophthalmia in Asylums and Residential Schools," brought this subject to the notice of the profession and the general public. As a result of this, and chiefly by the personal interest and

*Read before the New York County Medical Society, January 26, 1903.

efforts of Dr. Derby, a committee was appointed by the New York Academy of Medicine, in 1886, to investigate and report on the subject of contagious eye diseases in asylums and residential schools in this city.

This committee, composed of some of the best-known members of the profession, inspected fifty-one institutions, examining a total of 12,684 inmates, and finding 3,862 with some form of contagious eye disease—over 30 per cent.

Subsequently, an act for the better preservation of the health of children in institutions was drawn up and passed by the Legislature in June, 1886. The good effects of this law, and the great diminution in the number of cases of contagious eye diseases in these public institutions, was shown in a paper read by Dr. Derby, the consulting ophthalmologist of the Board of Health, in July of last year, in which he stated that the percentage of cases which had been perfectly enormous in some of these institutions—reaching as high as 50 per cent. of the inmates—had been reduced to from 2 to 7 per cent.

One of the most striking examples of what has been done by intelligent and persistent care and eternal vigilance is shown by the record of the Roman Catholic Protectory. In 1886 Dr. Mittendorf made an inspection of the Protectory, examining 2,137 children, finding 871 cases of contagious eye disease—more than 40 per cent. The percentage at the present time is something over 3 per cent. I can only add my testimony to that of Dr. Derby's as to the good work which Dr. Bradley has done in bringing about such excellent results, and the labor and care which he still exercises in maintaining an equally satisfactory state of affairs.

Many similar institutions, I have no doubt, can show just as good a record, and have had as careful and conscientious care as that given to the inmates of the Protectory by Dr. Bradley. I speak of the Protectory especially, because it is the only one of which I can give any personal testimony, and to show what can be done.

It must be remembered that in all these public institutions, especially in the Protectory, new cases are being constantly admitted. Were it possible to refuse admission to any child showing trachoma, it would, no doubt, be a very much simpler matter to control the disease in such an institution, and probably eliminate it altogether.

While all this good work was being accomplished in the various residential institutions, very little attention was being paid to the condition of the eyes of the children in the public schools. If children complained of their eyes, or if the teacher happened to notice anything the matter with them, they were either sent home to have their eyes treated, or referred to a school inspector. The attention of the Board of Health was called to this matter, both by the paper of Dr. Derby above mentioned and his personally advising with Dr. Lederle, and, in July of last year, a very careful inspection was ordered by the Board of Health, and made by competent men.

Thirty-six public schools were inspected, resulting as follows: Of 57,450 children examined 6,690 were found to have some form of contagious eye disease—over 13 per cent. Of these, 2,328 were severe trachoma, 3,243 were mild trachoma, and 1,099 acute purulent conjunctivitis. The percentage in the different schools varied from 3.2 to 22.2 per cent., the boys showing a larger percentage than the girls—boys, 3.6 to 28 per cent.; girls, 1 to 18 per cent.

The list of schools examined is as follows, those having the largest percentage of contagious eye diseases heading the list:

No. of School.	Location.	Pupils Examined.	Contagious Eye diseases.	Per-centage.
40	East 23d st.	1,005	224	22.7
34	Broome st.	2,550	560	21.9

These schools are mostly in the rather crowded districts, where we would expect to find the greatest number of cases. It is, however, rather remarkable that some of the schools in the most crowded districts do not show as large as percentage as some of the others in what might be considered a little better neighborhood. For example, the school showing the largest percentage is that in East Twenty-third street, being 22.7 per cent; whereas, some of the schools in the lower East Side show as low as 5 per cent.

From the statistics of the Board of Health I find that from the period of September 1, 1901, to January 1, 1902, 1,003 children were excluded from the public schools on account of some form of contagious eye disease.

From January 1, 1902, to June 1, 1902, 1,701 children were excluded—more for the half year than for the previous entire school year.

Since the school year was resumed in September, 1902, a systematic inspection of all the pupils was instituted by the Board of Health, with a result that from that time to the 1st of January, 1903, 20,316 children were excluded from attendance at school on account of some form of contagious eye disease.

Every precaution was taken by the authorities of the Board of Health to avoid mistakes of diagnosis on the part of the inspectors, all of whom were not familiar with eye diseases, by daily having at the Health Department a member of their staff who was perfectly familiar with eye diseases, and competent to make a correct diagnosis, to whom doubtful cases could be referred.

That many cases were unnecessarily excluded, all of us who are working in the various eye clinics of this city are aware. That the vast majority, however, were cases which required special treatment there can be little doubt; and, inasmuch as out of 6,690 children that were excluded for contagious eye diseases by the careful inspection made in July, 5,571 were found to have trachoma,

and from the following records showing the great increase of trachoma cases treated in the special hospitals, it is fair to say that a very large proportion of the 20,316 children excluded had trachoma.

The reports of the following institutions for the past three years show cases of trachoma as follows:

New York Eye and Ear Infirmary for 1900 shows 1,519 cases; for 1901, 1,211 cases; for 1902, 1,760 cases; and from October 1 to January 1, 1903, 2,323 cases—420 calls operated upon.

The Manhattan Eye and Ear Hospital for 1900 shows 592 cases; for 1901, 566 cases; for 1902, 823 cases; and from October 1, 1902, to January 1, 1903, 796 cases—296 cases operated upon.

The New Amsterdam Eye and Ear Hospital for 1900 shows 70 cases; for 1901, 91 cases; for 1902, 110 cases; and from October 1, 1902, to January 1, 1903, 488 cases—328 cases operated upon.

The Ophthalmic and Aural Institute for 1900 shows 297 cases; for 1901, 336 cases; for 1902, 355 cases; and from October 1, 1902, to January 1, 1903, 650 cases—350 cases operated upon.

From the above figures it is easy to see that from October 1, 1902,to January 1, 1903, which was the time during which this careful inspection of the public schools was being so assiduously carried out, there had been an enormous increase in the number of cases of trachoma treated at the four special hospitals above mentioned, and, of course, these figures by no means represent all the cases of trachoma which had been excluded from the schools, as many of them found their way to the various dispensaries and general hospitals. In fact, so overwhelmed were some of the special hospitals with trachoma cases sent from the schools and requiring operation, that it was impossible to deal with them.

This condition of affairs was brought to the attention of the Board of Health, and it was urged by Dr. Derby that the city make some provision to treat these cases. On the 17th of December, what is known as the Health Department Eye Hospital and Dispensary was opened at Gouverneur Hospital, and the surplus from the various hospitals, and the children excluded from school subsequent to that time, were directed there for treatment. From the opening of the hospital up to January 20, 3,591 new cases were treated—402 operated upon.

While there is a great difference of opinion as to what is and what is not trachoma, or whether it is contagious or non-contagious—all of which I trust will be settled, if not by the subsequent discussion, by the investigations and study which the interest in this subject has already suggested; for I may say here that the pathological department of the Board of Health has already seriously taken up the matter of investigating this side of it—and while it is not possible to say how many of the 20,316 children of the schools had trachoma, or any other disease of the eye endangering their own eyes or their fellow pupils, there can be no doubt, from the records of the hospitals above quoted, of the enormous number of cases of trachoma among the school children; and from that we can only surmise how much more there must be among the families of these same children in the densely populated sections of the East side.

The question, therefore, naturally suggests itself, how best to meet this evil. We have had demonstrated what can be done in the residential institutions by the inspection of all children for admission, isolation, and proper treatment, and after their admission to the main building the regular monthly inspection, treatment, and isolation whenever the slightest indication of a return shows itself; and, above all, the abolishing of all basins, bathtubs, and roller towels, and the instituting in their stead the shower bath, individual towel, and individual jet of water for washing purposes.

Were it possible in these various institutions to refuse admission to any applicant showing trachoma, or an active contagious inflammation of the eye, it would be a very simple matter to control the disease; and, as a remedy, it has been suggested that certain institutions be set apart for the care of all children who have trachoma or any contagious eye disease. This, of course, would seem an ideal solution of the difficulty in these particular institutions, but it seems hardly practical, and with the modern appliances for washing, isolation, and regular inspection, certainly a very excellent condition of affairs—as is shown in the Catholic Protectory—can be maintained.

The problem as regards the public schools, which are non-residential, is naturally a very different one, and I don't know that any better plan than that which is now being carried out by the Board of Health is feasible, which, in short, is the careful and constant examination of the eyes of the children, by the inspectors of the Board of Health, and by insisting that these children shall not be allowed to resume their places in the class-room until their eyes have been cured.

In addition to this the Board of Health has established a corps of trained nurses, who visit the homes of the children excluded from the schools, who explain to the parents the seriousness of the condition, direct them where to take the children for treatment, giving them some instruction as to the care of the eyes, the danger of contagion by the use of a common basin, towel, and so on. They also investigate, as far as they can, the condition of the eyes of the other members of the family. This, I think, is a most valuable adjunct to the school inspection. The number of nurses so employed is at present much too small; I trust it may soon be increased.

What seems to be most necessary in New York City, and which has been repeatedly recommended before, is a special hospital for the treatment of all contagious eye diseases. The energetic and expeditious way in which this need was met by the Board of Health, by temporarily establishing the Eye Department in Gouverneur Hospital, is a move in the right direction; and the good work which has been done there since it was started, and the practical needs demonstrated thereby, will hasten the establishment of a permanent institution of this kind.

Not only would an institution of this kind be a great benefit in taking care of trachoma cases, but it would be particularly useful in caring for cases of acute purulent conjunctivitis, so many of which we see at the clinics—especially during the summer—and are unable to take care of all of them as should be done in the hospital, for lack of accommodation.

One important point which I think should be considered, in examining the eyes of the school children, is that the inspectors should be men familiar with eye diseases, and perfectly competent to evert the upper lid, in order to examine thoroughly the upper cul-de-sac. I know that most of the inspectors do this, I also think that some do not, and, therefore, many cases which should be treated might very easily escape their observation.

The difficulties in providing men especially skilled in this work, by the restrictions of the civil-service law, I am perfectly well aware of, and I think too much credit cannot be given to Dr. Lederle and his able assistants for the excellent way in which they have met these unusual conditions and so success-

fully coped with this epidemic; especially in regard to the establishment of the Eye Department in Gouverneur Hospital, and the admirable way in which the work is being conducted there.

I wish here to extend my thanks to Dr. Lederle and to Drs. Bensel, Dillingham, Cronin, and Lyons of the Health Department, for the assistance I have had from them in obtaining the above statistics.

8 West Thirty-fifth Street.

A Case of Dysentery Due to Double Infection with the Uncinaria Duodenalis and the Amœba Coli.—Samuel B. Ward reports the case of a physician suffering from dysentery contracted in the Philippine Islands. On admission to the hospital he was having ten or twelve movements in twenty-four hours, with much griping and tenesmus. At this time, and subsequently, the stools were examined by Dr. George Blumer, director of the Bender Laboratory, with the result of finding both the ova of the uncinaria and the amœba coli. The patient was given a solution of thymol in alcohol, diluted with water to a strength of 1 in 2,500, with instructions to drink it instead of plain water. High rectal injections of the bisulphate of quinine, 20 grains in water, were given twice a day for six days, with some improvement, but without entire relief. The patient then fasted absolutely for forty-eight hours, and was then given the oleoresin of filix mas, one drachm in capsules every two hours and a half for three doses. followed four hours after the last dose by a saline cathartic, which produced six watery stools. Two days later neither the amœbæ nor ova of the uncinaria were found in the stools, but there was some pus. Recovery is satisfactory, although the patient has to be careful of his diet, and is somewhat easily tired.—*Albany Medical Annals.*

Report of a Case of Aortic Regurgitation and Stenosis and Mitral Regurgitation with Capillary Pulse.—Willard H. Sweet describes a case presenting the above-mentioned conditions. There was no obvious cause and no well-marked beginning of the man's valvular diseases. One of the remarkable features about the case is the absence of objective symptoms, which usually accompany such cases. Compensation must be well preserved, and the man's powers in this direction must be well-nigh limitless, for he has been under observation for about nine years, and is apparently as well now as when first seen. His freedom from angina would indicate that the coronaries are unobstructed and are performing their functions well. There seems to be a growing tendency to place less reliance than formerly on the mere existence of a murmur in the diagnosis of valve disease. One author declares that they are notoriously uncertain, especially the systolic murmurs. Some even might regard the stenotic murmur in this case as being due to roughness of the aortic valve or intima of the aorta, but it seems to the author that the very fact of the existence of this man's disease for so many years furnishes evidence of the beneficial effect of a co-existing aortic obstruction.—*Albany Medical Journal.*

Tuberculous Meningitis in Adults Occurring as a Terminal Event in Chronic Pulmonary Tuberculosis.—S. Vere Pearson, in conclusion of his study, emphasizes the following points: Tuberculous meningitis of this kind does not, as a rule, present clinically the well-marked characteristics of the disease seen in childhood. The duration of symptoms is shorter, the onset may be sudden or insidious, but in either case easily recognizable signs of meningitis are frequently absent, either throughout or until the last few hours. Retention of urine occurring in a patient with chronic pulmonary tuberculosis, when no local cause can be found, should always suggest tuberculous meningitis. So should curious mental or pseudohysterical phenomena, with a raised temperature, whether signs of a chronic tuberculous lesion are found or not. In patients dying of chronic pulmonary tuberculosis who have exhibited slight mental symptoms shortly before death, tuberculous meningitis is sometimes found post mortem when unsuspected, and when no other more definite symptoms of the complication have been present. It is almost invariably associated with general tuberculosis.—*The Clinical Journal.*

A Century of Arm-to-Arm Vaccination.—Eduardo Licéaga describes the method of arm-to-arm vaccination which has been practised for a hundred years in Mexico, the greatest care having been exercised as to the choice of candidates for propagating the virus. As to the results, it has been observed in the first place that persons vaccinated in this way remain immune during their whole lives. When there is a widespread epidemic, it is stopped in no time by at once vaccinating all persons who have not previously been so treated. The immunity which vaccination confers on infants is preserved during the whole of their lives. No Mexican physician has ever died of smallpox, even if he has been in practice for forty years. The same immunity has been observed in male and female nurses who attended smallpox patients. Experiments undertaken by order of the Supreme Board of Health of the City of Mexico show that vaccinations succeeded exceptionally well. Of 1,307 revaccinations only twenty-three were successful.—*Indiana Medical Journal.*

Report of a Case of Bilharzia from the West Indies.—P. Manson says that with the exception of Mesopotamia, Cyprus, and Mauritius bilharzia disease has hitherto been supposed to be peculiar to Africa. The author reports a case which shows that the parasite has a wider range. Personally, until he came across this case, he never encountered the disease in patients from the West Indies, but its occurrence in a white man from that part of the world practically proves that in certain of these islands, if not in all, it must be by no means uncommon amongst the colored population. The patient, an Englishman and a professional man, came to the author as a private case, complaining of vague symptoms, lumbar pain, headache, etc. As he looked anæmic, and came from a place where ankylostomum duodenale is very prevalent, and as the symptoms could not be accounted for, the author made an examination of his fæces for ankylostomiasis, and so discovered the ova of bilharzia. In this case, as so often happens in bilharzia, from the alimentary canal, the spine is placed laterally.—*The Journal of Tropical Medicine.*

Restoration of Sight in a Nearly Blind Cancerous Eye by Cancroin.—Albert Adamkiewicz reports the case of a woman of forty-two years who had previously been operated on twice for cancer of the breast. When seen by the author, there was a cancerous infiltration of the choroid of the left eye, with a partial loosening of the retina. Vision was reduced to the perception of light. Cancroin injections were begun at once. Infiltration of the scar of a former operation, and enlarged clavicular glands were favorably affected within a few days. Vision in the affected eye began at once; seven days after the first injection the patient could recognize the countenance of her husband, and moving objects near a window. Recovery of vision became practically complete, and pains which had existed in the patient's hands and feet disappeared.—*Medicine.*

Coffee-drinking.—Notwithstanding the scare advertisements of health-substitutes for coffee, there is no cause for apprehending danger to the race at large from coffee-drinking. After generations of almost universal coffee-drinkers, our own times see men of gigantic intellect in all realms of activity; our athletes are able to make sudden bursts of effort equal to any in history, and our soldiers acquit themselves manfully in fatiguing campaigns in torrid climes. The life insurance companies, constantly warring against all that lessens longevity or conduces to abnormal organs, nerves, and actions, seem content to accept the use of coffee as one of the ordinary elements of every-day life.—*American Journal of Pharmacy.*

THE TENEMENT-HOUSE PROBLEM.

THE question of the sanitary housing of the tenement population of New York is of such vast importance to all of the social elements that make up the city, especially in connection with the present discussion of the subject in both houses of the Legislature, that it becomes of immediate and vital interest to the medical profession.

There is no question, in the first place, of the elementary principle that it is desirable that the tenements should be constructed in such a manner as to secure to their inhabitants the largest possible amount of light and air, and, secondly, in such a way as to secure the privacy and the maximum comfort of each family. It would not be difficult to meet all of these requirements in the construction of tenements in this city were such buildings built at the public expense and given to the poor, either without price or at a fixed rental within their means, as is done in respect to our public schools. But this is not, nor will it ever be the condition of tenement occupancy, so that in the construction of sanitary tenement-houses an important and vital limiting factor demands preëminent consideration, and that is, what rent is the tenement dweller able and willing to pay? Tenement-house owners and builders, however well disposed, look upon the matter from an investment standpoint, and while competition may be safely relied upon to limit the profits of tenement investments, on the other hand, all legislation which renders the construction and maintenance of tenement-houses more costly will inevitably increase as a primary effect the rent-paying burden of the tenement dweller. This, the main factor of the tenement-house problem, which *the present tenement-house law does not solve.* In other words, the present tenement-house, constructed in accordance with the tenement-house law, is too expensive for the pockets of the tenement-house dweller. Land for building in the crowded tenement districts of Manhattan Borough, especially in the Tenth, Eleventh, and Seventeenth Wards on the east side, is an extremely expensive commodity. The large light and air shafts, the wide halls, and the open court-yards, while extremely desirable add very largely to the cost of a tenement apartment in these houses. A tenement with four families to the floor, previous to the going into effect of the Act of 1901, could be constructed upon a 25x100 lot, and such tenements when well constructed and in accordance *with the law* which permitted the covering of only 75 per cent. of the lot, were fairly satisfactory structures, especially from a cheap rental standpoint.

Under the Act of 1901 but 70 per cent. of the lot can be built upon, while the light shafts and the increased width of the halls further diminish the available space for apartments, so that it is found in practice that a 40x100 lot is required for a four-family-to-the-floor tenement. This increases the cost of an apartment about 40 per cent. Thus three or four rooms in the old dumb-bell shaped tenement could be hired for an average rental of from ten to fourteen dollars per month in the east side tenement district, while in the buildings constructed under the present law a four-room apartment rents at from eighteen to twenty-two dollars per month. Very few three-room apartments are built, the light shafts not readily admitting of such a division of the floor. Furthermore, in order to increase the renting capacity of the house, builders have added an additional story, so that within the past three years tenements are built seven stories high, while formerly five-story tenements were the rule. As a result of this, myocardial affections and bronchial asthma are becoming frequent conditions amongst the tenement dwellers on the upper stories of these buildings. Several physicians practising in the tenement districts have developed heart affections from excessive stair climbing, and coal and ice dealers who supply these families with their commodities suffer from the same conditions. The suggestion that elevators be placed in such buildings would mean another increase of 30 per cent in the rent of the tenement.

Tenements constructed under the Act of 1901 filled with four to six-room apartments costing from eighteen to thirty-two dollars per month are beyond the means of the tenement dweller. He has therefore filled the old tenements which could be hired for the old prices, so that even undesirable rooms which before the passage of the present act were difficult to rent are now sought for with avidity. There is not enough of these, however, to go around, so that the balance of the tenement dwellers have been compelled to occupy the new houses. The number of these new buildings which have been constructed under the present law have been insufficient to keep pace with the normal annual increase in the tenement population of the city, so that even these buildings have been rented as soon as finished. But in these new buildings the tenement dweller no longer retains the four rooms for his wife and children, but is compelled to take in lodgers, frequently three or four, to help him pay the rent. The privacy of the family life is destroyed. The sanctity of home is broken. Parents, growing daughters, and sons, share the small four-room apartments with male lodgers. All this is the result of the high rents which necessarily result from the otherwise excellent provisions of the Act of 1901, so that this act intended to benefit the poor has its drawbacks from a sanitary, an economic and moral standpoint.

It might be claimed that the tenement dweller under these conditions would find it advisable to move to less thickly inhabited districts where land

and rents are cheaper. Such removal would mean at least three dollars per month for each working member of the family for car fare. It would mean rising an hour earlier in the morning and traveling on crowded cars after a day's work in the evening. It would also mean purchasing his lunch at mid-day or eating cold food which he had brought with him. No, the tenement dweller must account for every penny, and traveling to and from his work is a luxury in which he cannot indulge.

Figures obtained from the Building Department of this city would seem to show that this act is in a fair way to deprive the poor of their tenement homes, the only homes they can afford. The act went into effect in April, 1901.

Tenements built in the Boroughs of Manhattan and The Bronx, including apartment houses of the better class, were:

In 1898, 1,584, of which 166 cost less than $15,000 each; 1899, 2,299, of which 185 cost less than $15,000 each; 1900, 704, of which 47 cost less than $15,000 each; January, February, and March (three months), 1901, 350, of which 14 cost less than $15,000 each; April (one month), 1901, 741, of which 50 cost less than $15,000 each; and under the new law, May to December (eight months), 1901, 76, of which 14 cost less than $15,000 each; 1902, 227, of which 1 cost less than $15,000.

In the year 1900 the Building Department enforced the old law more strictly, hence a falling off in the number of tenements constructed from 2,299 in 1899 to 704. In the first four months of 1901, 1,091 tenements were constructed in order to take advantage of the provisions of the old law before the new law went into effect. In the balance of the year 1901 only seventy-six tenements were erected under the new law. The smallness of this number might be accounted for by activity in building before the new law went into effect. But the whole number for the year 1902 was only 227 tenements as compared with 1898, which was a normal year for our purposes and during which 1,584 tenements were built. And only one tenement built in 1902 cost less than $15,000 as compared with 166 tenements in 1898 at less than $15,000 apiece.

It must, therefore, be assumed from these figures that the construction of tenement-houses in compliance with the provisions of the Act of 1901 is so extremely prohibitive that capitalists and builders, notwithstanding the increased rental upon which they have insisted, and the excessively low rate of interest at which money can be borrowed, have considered the building of tenement-houses an unprofitable investment. Another year or two of so limited an amount of tenement construction will mean suffering to the tenement dweller, both for lack of houses, and even a greater increase in the present unbearable rent tax upon his energies.

We do not consider that the Act of 1901 has solved the question of the housing of the poor. The present tenement-house law urgently demands modification. Tenements must be sanitary, tenements must have plenty of light and air, but, above all, tenements must be constructed within the means (pecuniarily) of those who must hire, pay for and live in them.

CARE OF THE INSANE IN NEW YORK STATE.

The entire annual report of the State of New York Charities Aid Association to the State Commission in Lunacy has just been published. In the Medical Record, January 17, the first half of this report—which was given out some weeks ago—was made the subject of editorial comment, and opinions were expressed with regard to the working of Governor Odell's legislation respecting the management of the institutions for the insane in the State.

In the present article it is proposed to discuss, somewhat briefly, a few points contained in the report which were not touched upon in the former notice. Referring to the care of the consumptive insane, the report draws attention to the fact that there seems to be a large and increasing number of this class of patients. The proportion of deaths due to this cause at the Willard State Hospital during the fiscal year 1901 was 18 per cent.; at the St. Lawrence State Hospital about 25 per cent.; at the Manhattan State Hospital, West, the disease was diagnosed in 103 cases during the year. The facilities for treatment at these State hospitals are inadequate, and most of the other State hospitals have practically no facilities for isolation and proper care. It is suggested in the report that one of two courses in order to bring about improvement should be pursued.

The recommendations are as follows: That each State hospital should be equipped with suitable frame cottages built with reference to securing the greatest amount of light and air and sunshine. These cottages might be so simply and inexpensively built that if they became infected they could be destroyed without any appreciable loss to the State. Another solution of the difficulty would be to transfer all tuberculous patients to the State hospital, where climatic conditions are most favorable for the treatment of such cases. If the State is to establish a new State hospital in the Lake Champlain region it might be well to consider this matter in deciding upon the plans for construction. The new State hospital might include a colony for the insane suffering from phthisis to which patients from all parts of the State could be transferred, to the safety of other patients, to the great relief of the various hospitals, and to the betterment of the physical and mental condition of the patients afflicted.

The successful experiment of Dr. Macdonald at the Manhattan State Hospital, East, in providing camps for the phthisical insane is favorably noticed in the report and the recommendation is made that this example should be followed by other State hospitals which are located favorably. For instance, the Rochester and Buffalo State hospitals might have their comparatively small acreage supplanted by land on the shores of Lakes Ontario and Erie, respectively, where patients might enjoy a delightful and improving vacation. Most of these institutions are so situated that rivers, lakes, or woods are easily accessible, and pleasant camping places would not be difficult to find.

The report severely criticises the policy of the new management in reducing the dietary, and the committee of three State hospital superintendents appointed by the State Commission in Lunacy to

look into the matter made this statement: "We think it is generally recognized that the diet of acute cases must be rich in nutrition and sufficiently varied to produce results. Many of the cases admitted to public institutions for the insane suffer from privation and various other evils that are associated with it. Some of these upon admission are acute and recover largely as a result of watchful care and the absorption of proper nourishment. Other cases are received who are chronic and who need to be built up. Experience teaches that when a sufficient amount of food is not provided for the general average run of patients in an institution, that the patients manifest the evil effects by becoming more restless and disturbed, and hence require greater care, which always involves increased expense. By keeping up the body to as high a physiological standard as possible, we can keep our wards comparatively quiet, and there is, therefore, a practical reason why we should properly nourish even the chronic and disturbed. We believe it is of the utmost importance to provide a nutritious and varied dietary."

Since the views of the committee were made public the dietary has been increased, but in commenting upon this alteration the report says: "Whether the increase allowed is sufficient is a question which depends for its answer upon what standard of living we accept as proper for the insane. If the view of physiologists that a generous diet is desirable be accepted, then the present dietary is not satisfactory. The medical superintendents in their efforts to coöperate with the administration in carrying out a policy of rigid economy, have, perhaps, accepted a lower standard than they would have been inclined to recommend for the best interests of the patients."

The report also passes strictures upon the tendency of the present management to decrease the number of employees at the State hospitals. The State Commission in Lunacy in its report for the fiscal year 1901 deprecated a further decrease in the number of helpers, but the State Charities Association report states there has been during the past year a reduction in wages of employees amounting to $15,343.59.

It would seem that the chief aim of those who are now in control of the State hospitals is to conduct these institutions as cheaply as possible. Undue extravagance in the management of any public establishment ought to be checked, but at the same time, the first and principal object should be the well-being of its inmates, and especially when these inmates are insane. The taxpayer's money is expended to greater advantage in caring for the sick in body or mind than in lavishing it for mere selfish political ends.

EXPERIMENTS WITH FORMALIN.

Drs. W. H. Park and W. A. Payne have been conducting recently a series of experiments for the purpose of testing the efficacy of formalin in septicæmia. The investigations in question were made in the bacteriological laboratory of the Health Department, and it appears that the results obtained have not vindicated the claims advanced by Dr. Barrows, that formalin is a valuable remedy in puerperal sepsis by reason of its antitoxic action. The experiments were performed upon rabbits, and showed that when a formalin solution of the strength used in Dr. Barrows' case was injected into a number of rabbits inoculated previously with a streptococcus germ, the result was that these rabbits did not live so long as an equal number likewise inoculated with a streptococcus germ, but which had not been injected with formalin. With larger injections of formalin, it was found that the formalin lessened the resistance of the body to the invasion of bacteria. Dr. Park concluded, as an outcome of these and other experiments, that the amount of formalin injected by Dr. Barrows had very little effect upon bacteria, retarding for a few hours only the rapidity of the development of the germs.

The formaldehyde combines with the albuminous part of both the bacteria and the blood and is consequently injurious to both. The affected bacteria quickly reproduce, and the formalin, being already consumed by the chemical combination that has taken place, has no further effect. The injury to the blood cells, however, is not healed so quickly. In short, the experiments would seem to show that formalin is of no use in septicæmia, but is a source of some danger.

The fall in temperature produced by the injection of this agent, is not so much owing to its action as to the presence of the solution. The article which appeared in the Medical Record of January 31 gives a clear presentation of the case for and against formalin as a remedy in septicæmia and the investigations made by Drs. Park and Payne tend to confirm the opinions therein expressed.

Sleeping Sickness of Africa.

This mysterious and obscure disease is raging with exceptional virulence in Uganda at the present time, some districts having been entirely depopulated. Dr. Low, who was sent out by the London School of Tropical Medicine to that part of Africa to investigate into the origin, cause and course of the malady, has given a description of the manner in which some thirty thousand persons have been carried off by sleeping sickness.

The London *Hospital*, December 27, has the following account: "The so-called 'sleeping sickness' has been known for many years as an endemic disease of the West Coast of Africa, usually confined to the belt lying between Senegambia on the north of the equator, and Loanda on the south, but extending into the Kongo at least as far as to Stanley Falls, and it was formerly occasionally imported into the West Indies, but has not been seen there since the abolition of the slave trade. Between Uganda and the Kongo there is no trade route, and the precise time and manner of the introduction into Uganda are unknown. Scientific inquiry seems to show that the malady is essentially a chronic form of meningitis, that it is produced by the presence of a germ presumably bacterial, and that it is communicable from person to person through channels which have not as yet been clearly demonstrated, the general fact of infectiveness not being doubtful. It seems to differ widely from the only form of epidemic meningitis known in Europe, the so-called 'cerebrospinal,' in its chronic character, as well as in its almost invariably fatal issue, recovery or cure being practically unknown. The early symptoms are so slight that they would easily escape the notice of the unpractised observer." The disease pursues

its course before reaching a fatal termination in periods of from one to six months, and is, according to Dr. Low, one of the mose fatal diseases known to man, as no treatment appears to exert the slightest influence on the progress of the malady or in staying the termination. Europeans have not thus far fallen victims to sleeping sickness.

Retirement of Dr. Malcom Morris.

Mr. Malcolm Morris, the well-known surgeon, and decidedly one of the best and pungent writers engaged in medical journalism, with the incoming of the new year has retired from the editorship of the London *Practitioner*. Mr. Morris, who conducted the journal in question for eight years, was recognized in England as a medical editor *sui generis*. Referring to his own work in his valedictory remarks in the *Practitioner*, December, Mr. Morris laments that he, in medical journalism, like Lord Rosebery in politics, has ploughed a "lonely furrow." He may, however, console himself with the thought that his labor has not been in vain, nor unappreciated. He was fearless in criticism, and thus could not avoid on occasions giving offense, but his independent and fair attitude on all questions of moment which occurred in the medical world did much good and won him many friends.

It seems to be the impression that wit or humor is altogether out of place in a medical journal, and that unless contributions are solid and grave they are unbefitting the dignity of such a publication. Mr. Morris did not regard the matter in this light, and made his editorial columns bright and enlivening reading. He was the pioneer of special numbers, and some of the issues of the *Practitioner* devoted to a consideration of certain diseases are the best of the kind ever published. It is rumored that the late editor of the *Practitioner* does not intend to retire from journalism, but will write for weekly English journals. It is certain that the medical profession of America, many of whose members know Mr. Morris, will wish him well in whatever he undertakes.

The Milk Question and Mortality Amongst Children Here and in Germany.

Germany has gained the reputation within recent years of having made such strides in all matters relating to public health that she is now conceded to be equal, if not superior, in these respects, to any country of the world. The death rate among children is generally considered a fair criterion of the height to which preventive sanitation has been carried, and the purity of the milk supply is the base upon which the health of the children depends. Such being the case, one would naturally conclude that the mortality among children in the cities of Germany would compare favorably with that of any cities of the world.

According, however, to Emile Berliner, who has been making investigations into the mortality of children in a certain city of Germany, the conditions are worse than in a city of similar size in this country. Hanover and Washington were the places selected for the purpose of comparison. Hanover has long been looked upon as a model German city. Its water supply is beyond reproach, and in addition, it has been for years the seat of a magnificent institute of technology, while its streets have been always kept scrupulously clean, and its gymnasiums and bathing establishments are sources of pride to all its citizens. On the other hand, although Washington is a particularly clean town, and contains a large number of parks and open spaces, its water supply is obviously open to criticism and a third of its population are negroes.

From a consideration of these facts, it might be thought that the death rate of children in Washington would be far greater than in Hanover. The mortality among children in Hanover is 60 per cent. greater than in Washington.

Berliner traces the high mortality among children in Hanover to impure milk, due to faulty inspection, and concludes that most children's diseases are closely connected with the milk supply, and that the city which is most vigilant on the milk question and has a system of inspection covering every stable from which milk is furnished to its citizens, is ahead in civilization of the city where milk laws and dairy inspection do not exist, or are but superficially enforced.

In Hanover they have practically neither milk laws nor inspection of stables. The only punishable offense is the addition of water. In Washington they have pretty good, though not perfect, milk laws, and inspection is all that can be expected under the circumstances.

The statistics of infant mortality in Washington and Hanover would seem to offer convincing proof that pure milk is necessary for the preservation of the health of young children.

The Spitting Nuisance and Dogs.

During the past week this city has passed through a most successful dog show. During the same week many arrests were made for spitting in public places, most of which latter were unprovided with cuspidors, and consequently the prisoners were usually discharged after spending a night in the lockup.

It will be too bad if a really good law gets brought into general disrepute because of absurd practices.

New York requires a new health ordinance, or at least a ladies' society for the encouragement of street-bred dogs.

No prize was given for this class at the kennel show. There were blue and red ribbons for all other kind of dogs, but not even a piece of red tape was offered for the dog that had been taught to go into the gutter in response to nature's call. The defiled condition of the sidewalks in certain parts of this—in many other respects—fair city, is not only a disgrace but, from the health side, it has a very decided importance. Many diseases by this means are transmitted from the dog, as is well known, and the amount of unwholesome material taken into dwellings upon the shoes and trailing skirts for any single day even must be enormous.

The Street Cleaning Department is doing good work cleaning up between the sidewalks after horses, but no one cleans up intentionally after the dogs.

Several ways of combating the evil suggest themselves. Owners who insist upon this unfair use of the sidewalk should have their dog tax doubled and be fined to boot. The funds thus raised could be given to the Street Cleaning Department, whose duties should be made to include sidewalks thus defiled. Until the evil is in a measure decreased all women, especially members of the anti-spitting league, and more particularly those who keep pet dogs and take them for a morning "airing" on Fifth and Madison avenues, should be prohibited from wearing any long garments.

Medical Inspectors Dismissed.—Seven medical school inspectors of the New York City Board of Health have recently been dismissed for falsifying their vaccination reports.

News of the Week.

The New Scarlet-fever Antitoxin.—The cabled dispatches to the *New York Herald* announcing the discovery of a new antitoxin for scarlet fever, endorsed as they are by interviews from Professors Baginsky and Aronson of Berlin, are well calculated to command the respectful attention of the medical profession on this side of the Atlantic. So far the remedy has been employed in one case in this city under the care of Dr. Louis Fischer and with quite satisfactory results. A detailed clinical account of this and probably of other cases will appear in an early issue of the MEDICAL RECORD.

St. Mary's Free Hospital for Children.—On Wednesday of last week additions to this hospital, consisting of two new wards, provided through a bequest of Charles A. Contoit, a new chapel, which is in the same building as the wards, and a new building to be used for domestic purposes, were opened. Beginning thirty-one years ago with a small dwelling-house, which was rented from year to year, this institution has grown until it now has 100 beds and an ideal equipment. The hospital plot abuts on 34th street, 35th street, and Ninth Avenue. In 1900 a model of one of the wards was sent to the Paris Exposition and a gold medal was accorded to it.

The Typhoid Fever Epidemic in Ithaca.—The typhoid situation at Ithaca, N. Y., is reported to be very grave. The inspectors of the Board of Health reported on February 17 that there were then 449 cases of the disease in the city. Nine deaths have occurred among the students at Cornell University. An inspection of the creeks from which the water supply is derived has shown them to be almost indescribably filthy, the water being contaminated everywhere with leakings from pigpens, barnyards, and privies located along the banks of the streams.

A Tuberculosis Camp Suggested.—At a meeting of the New York City Board of Health recently it was decided to recommend to the Mayor and, if he approved, to the Board of Estimate and Apportionment, a plan to establish a tuberculosis camp somewhere outside of the city. The tuberculosis committee of the Charity Organization Society has been advocating the erection of a tuberculosis hospital—something on a very large scale that will cost many thousand dollars. The Board of Health thinks that this is too expensive an experiment, but feels that some institution is very necessary to the city. The plan is to select a piece of ground away from any village, on high land, about fifty miles from the city, and then to set up substantial but comparatively inexpensive tents. Each tent will hold two or three people, and will cost approximately $100.

Consulting Physician to Manhattan State Hospital.—Dr. Carlos F. Macdonald, former President of the State Lunacy Commission, has been appointed by the present State Commission Consulting Physician to the Manhattan State Hospital, a position which his large experience as an alienist eminently entitles him to fill.

Medical Examiners for the Street Cleaning Department.—A bill amending several sections of the law affecting the New York City Street Cleaning Department has been introduced into the legislature at the instance of Dr. Woodbury. Among other changes the bill provides for six medical examiners in the department instead of three as at present, and for six veterinary surgeons instead of five.

Foot-and-Mouth Disease.—It is reported that the epidemic of foot-and-mouth disease in New England, which was supposed to be practically extinct, has begun to increase near Boston, where most of the cases recently had been concentrated, and there is considerable anxiety over a possible spread of the disease.

The Plague in Mazatlan continues, several deaths from the disease being recorded daily. The Mersin serum has been used in a number of cases with apparently excellent results. The disease is smoldering still in San Francisco, but some of the local papers are even yet denying the existence of the disease and berating every one who mentions the subject.

Dr. Thomas D. Coleman of Augusta, Ga., was recently elected president of the Board of Health of that city. He is a graduate of New York University Medical School in the class of 1890, and is professor of medicine in the Medical College of Georgia. He was a member and secretary of the Augusta Board of Health for some time before his election to the presidency.

Amendments to the Public Health Law.—Senator Stewart has introduced a bill into the New York State Legislature amending the present public health law in the following particulars:

(1) In all buildings and institutions, owned, maintained, or controlled by the State, the plans for all water supply, sewerage, sewage disposal, and garbage disposal works shall be subject to the approval of the State Commissioner of Health before being adopted or constructed.

(2) The State Commissioner of Health shall appoint for each municipality (except such municipalities as are now exempt under section 32, article 2, of the Public Health laws, a competent physician not a member of the local board of health to be the health officer of the municipality. This health officer may be removed by the State Commissioner of Health after a hearing. He need not be a resident of the municipality for which he is chosen, but unless he is such resident he must reside in an adjoining town.

(3) Additional compensation is allowed for extra services of health officer, for extra hazardous work by reason of epidemic or otherwise. Any health board may allow traveling expenses for delegates attending the annual sanitary conference of health officers.

(4) Local boards of health shall enforce general vaccination of all persons when required to do so by the State Commissioner of Health, who is hereby authorized to make such a requirement when in his judgment such action is necessary for the protection of the public health.

(5) For removal of nuisances health boards may use any money in the hands of the board or may call on the city council, village trustees, or town board, or may borrow the same on the credit of the municipality, to be returned when collected from the persons responsible.

The Eleventh International Congress of Hygiene and Demography will be held in Brussels from September 2 to 8, 1903. The Secretary-General of the Congress is Dr. F. Putzeys of Brussels.

Smallpox in Pennsylvania.—It is reported by the Secretary of the Pennsylvania State Board of Health that there were reported from that State during the month of January 940 cases of smallpox with fifty-five deaths.

The Typhoid Fever Epidemic in Philadelphia.—For the week ended February 7 there were reported to the Philadelphia Board of Health 329 cases of typhoid fever with twenty-three deaths, as against

325 cases and thirty deaths during the preceding week.

College of Physicians of Philadelphia; Section on General Medicine.—At a stated meeting, held February 9, Dr. Augustus A. Eshner presented a case of cirrhosis of the liver with splenomegaly in a young man. The patient was a laborer in a tannery, nineteen years old, who exhibited jaundice and enlargement of the liver and spleen and gave a history of periodic alcoholic excess. He denied venereal infection, and there was no evidence of ascites or of visceral or glandular disease. There was a moderate degree of anæmia, involving both corpuscular elements and hæmoglobin in like proportion, and the number of leucocytes was diminished. There was a history of chills and fever, with the presence of malarial plasmodia in the blood. The condition was at first thought to be of one of splenic and hepatic enlargement in connection with malarial infection, but it was subsequently decided to be one of hypertrophic cirrhosis of the liver with splenomegaly due to alcoholic excess, perhaps aggravated by malarial infection. The case presented many of the symptoms of so-called splenic anæmia. Dr. Joseph Sailer presented a case of congenital cyanosis occurring in a girl, twelve years old, in whom the condition had been accidentally observed while at school. Cheeks, nose, lips, and tongue, as well as hands and feet, were purple, the fingers and toes being, besides, elongated and thickened at their extremities. The heart was considerably enlarged, but only an uncertain and doubtful murmur was audible at the apex. The number of red blood-corpuscles and the percentage of hæmoglobin were markedly increased above the normal. The lesion was thought to consist in a deficient interventricular cardiac septum. Dr. George William Norris read a paper entitled, "A Contribution to the Study of Human Blood-pressure in Some Pathological Conditions," in which he recorded the results of observations made upon persons in health, cases of typhoid fever, pneumonia, nephritis, lead-poisoning, and other conditions. Dr. Wm. B. Stanton presented a communication entitled, "A Practical Clinical Method for the Determination of Blood-pressure in Man, with Some Remarks on the Methods Hitherto Employed." He pointed out the necessity and the importance of making in reasonably rapid succession determinations of both the systolic and the diastolic pressure, and he demonstrated an apparatus that he has devised for the purpose. He applies to the member selected for observation a rubber tube, flattened to a width of three and one-half inches and surrounded by a covering of inelastic material, to prevent outward distention. This is connected by means of an inelastic tube with a mercurial manometer, and with the aid of a special valve the blood-pressure can be speedily determined under various conditions. Dr. David Riesman read a paper on "Desquamation in Typhoid Fever." He pointed out the rarity of this condition, and reported two cases in which it had come under his observation, during convalescence, independently of previous sudamina or erythema, the exfoliation being in the one case of a branny character and in the other coarsely squamous.

Philadelphia Pediatric Society.—At a stated meeting, held February 10, Dr. M. H. Fussell exhibited "A Patient with Congenital Heart Disease," occurring in a girl, four years old, who presented cyanosis of the lips, tongue, fingers and toes, and also clubbing of the digits, with marked dyspnœa on exertion. The heart was greatly enlarged and a low-pitched systolic murmur was audible, most distinctly at midsternum. The eyegrounds exhibited great enlargement and tortuosity, as well as fulness, of the vessels, and inflammatory alterations. Dr. S. McC. Hamill read the report of "A Case of Congenital Heart Disease with Interesting Eye-findings." This patient was a child of twelve, who, in addition to cyanosis and clubbing of the ends of the fingers, presented enlargement of the heart with a systolic murmur at the third intercostal space on the left close to the sternum, and changes in the eye-grounds similar to those described in the case of Dr. Fussell. Drs. Arthur Van Harlingen and Henry K. Dillard, Jr., read a communication entitled "Some Notes on the Employment of Epicarin in Tinea Tonsurans and Tinea Circinata." They employed a tincture and ointments of varying strength, and the results were on the whole satisfactory. Dr. D. L. Edsall presented a communication entitled "A Preliminary Note on the Nature and Treatment of Recurrent Vomiting in Children." He had observed that in cases of this kind the breath has an odor of acetone, which is present also in the urine, together with diacetic acid and oxybutyric acid. He therefore concludes that a condition of acid intoxication is present, upon which the vomiting is dependent. Accordingly he recommends the administration of alkalies, such as sodium bicarbonate, in as large doses as can be given; for instance ten to thirty grains every hour, as soon as premonition of the attack appears. He has by this means been enabled to abort numerous attacks and to prevent recurrence of the disorder. His own observations have been confirmed and supplemented by those of others. Dr. I. Valentine Levi read the report of "A Case of Cystitis Due to the Colon Bacillus." The patient was a boy of twelve, who, in a spirit of experiment, injected bath-water into the urethra through a soft rubber syringe that had been used for administering enemata. Violent cystitis developed, and in the urine the colon bacillus was found. Dr. Levi cited also cases in two adults in which abscess of the kidney developed, the colon bacillus being found in the urine.

Pathological Society of Philadelphia.—At a stated meeting, held February 13, Dr. Randle C. Rosenberger read a paper entitled "Bacteriological Examinations of the Blood," in which he related observations of his own and cited those of others in which bacteria were found in the circulating blood. Dr. Arthur E. Dare made demonstration of a new alkalimeter, in which the blood is neutralized with tartaric acid, the transition from alkaline to neutral reaction being manifested by disappearance of the lines for oxyhæmoglobin as determined by spectroscopic examination. The apparatus was employed in a large number of observations and showed that, among other things, the alkalinity of the blood was diminished in all cases of typhoid fever in which a positive serum-agglutinating reaction was obtained, but not in such in which the reaction was wanting. Dr. Judson Daland presented a communication entitled "Case of Bubonic Plague, with Microscopic Slides." The case had been seen during a visit to Honolulu and presented characteristic features of the disease. The bacteria were obtained from one of the enlarged glands. Dr. Joseph Walsh read a paper entitled "Tubercle Bacilli in the Urine." He stated that among some sixty specimens of urine from patients suffering from pulmonary tuberculosis tubercle bacilli were found in about forty. Although negative results were obtained from inoculation experiments, the fact that the organisms were not smegma bacilli was shown by the circumstance that they did not

exhibit the staining reaction of the latter, while they were not found in the urine from individuals not suffering from tuberculosis. Dr. Richard M. Pearce presented a specimen of small intestine exhibiting extensive and profound ulceration and also the enlarged spleen from a fatal case of typhoid fever in a child two years old.

Philadelphia County Medical Society.—At a stated meeting held February 11, Dr. J. Norman Henry read "A Report of Nephropexy in a Case of Chronic Nephritis." The operation was performed on both kidneys, the capsules being detached and the organs placed in proper position. Symptoms of uremia developed, however, in a short time and death resulted. Dr. Orville Horwitz read a paper entitled "An Inquiry into the Value of the Irrigation Method as a Means of Aborting and Treating Acute Specific Urethritis." The results of this study showed that while, under certain conditions, the treatment of gonorrhœa by means of irrigation with hydrostatic pressure is indicated, in general the method is not to be commended, as it fails, as a rule, to abort the disease and it is often attended with undesirable sequelæ. Dr. Alfred Gordon read a paper entitled "Trunecek's Serum and Its Value in Disturbed Cerebral Functions Caused by Circulatory Changes, with a Report of Twelve Cases." The serum consists of sodium chloride .92 grams, sodium sulphate 0.44, sodium phosphate and potassium sulphate each 0.40, sodium carbonate, 0.21, and distilled water sufficient to make 100 grams. This is injected subcutaneously. The following modification has been recommended for internal administration: Sodium chloride 10 grams, sodium sulphate 1, calcium phosphate and magnesium phosphate each 0.75, sodium carbonate 0.4, sodium phosphate 0.3. This mixture is to be divided into thirteen capsules or cachets, and one administered from three to six times daily. The results in most of the cases were satisfactory.

Abolition of the Office of Coroner.—A bill to abolish the present system of coroners in the city of New York has been introduced into the State Senate. The bill, introduced by Mr. Elsberg and now in Committee on Cities, provides abolition of coroners and substitution of medical examiners—six for Manhattan, four for Brooklyn, two for Queens, two for the Bronx, and one for Richmond. Change commences September 1, 1903. Medical examiner must be "learned in pathology," and must have been a licensed practitioner of medicine in New York City for five years preceding appointment. Examiners shall be appointed from present coroners' physicians or from an eligible list prepared by the Civil Service Commission after special examination therefor. Salary $3,500 per year. Board of Health may appoint clerks, stenographers, etc., and adopt rules prescribing the duties of the medical examiners and aids. The medical examiners shall have the powers and perform the duties of coroners in so far as they are specified for the determination of sudden or suspicious deaths. Reports of such deaths shall be made to the Department of Health, one of the medical examiners, or a police officer. The medical examiner must proceed to where the body lies and take possession and exclusive charge of the same; he is also made the temporary custodian of all letters and articles found on the body, and must, after sealing them, turn them over to the district attorney or to the court. Autopsy, if found necessary, must be made in the presence of a district attorney's representative and a police officer. Full written report of findings must be forthwith filed by the medical examiner in the Department of Health. Inquiry heretofore made by coroner is to be made by city magistrate. The city chamberlain is to exercise all functions of the former coroner when not otherwise specified in this bill. One section refers to the chamberlain's duties in connection with the property of one so deceased which has been turned over to him by the medical examiner. The use of the term "medical examiner" is unfortunate, inasmuch as each one of the members of a State board of medical examiners is a medical examiner, and this duplication of the term may lead to confusion.

A Baby Hospital for Harvard.—In addition to the infirmary recently presented by Mr. Stillman, Harvard University is to have a hospital for the accommodation of fifty babies. The hospital, for which plans have been drawn up, is to be built in connection with the proposed new Harvard Medical School near the Fenway. It will cost about $140,000, and when finished will be the most complete and perfect of its kind in the world. The hospital will be a gift of the Class of 1901 in memory of Thomas Morgan Roth. A memorial laboratory is contained in the gift.

A New Eye and Ear Hospital for the Bronx.—A new hospital and dispensary, to be called the Bronx Eye and Ear Infirmary, was incorporated recently at Albany under a permit from the State Board of Charities. The incorporators were Drs. Charles H. McIlwaine and Everett M. Raynor and Messrs. Christopher H. Roberts, James C. Mackenzie, and James Dalton. The dispensary, which is open daily, except Sunday, from 2 to 4 P.M., is located at 660 East One Hundred and Forty-seventh street.

Obituary Notes.—Dr. Caleb W. Hornor died at Bryn Mawr, Pa., on February 8 at the age of seventy-four years. He was graduated from Jefferson Medical College in 1849, and he served as surgeon in the United States Army during the Civil War.

Dr. John Homans died at his home in Boston on February 7. He was a graduate of the Harvard Medical School in the class of 1862. After graduation he served as an assistant surgeon in the navy during the Civil War, and later was surgeon-in-chief of the First Division, Nineteenth Army Corps. He was one of the attending surgeons to the Massachusetts General Hospital, and was a member of the Massachusetts State Medical Society.

Dr. John J. Conway died of pneumonia at his home in Brooklyn on February 13, at the age of forty-four years. He was a graduate of the Long Island College Hospital in the class of 1880.

Dr. George Harris died at Bridgeton, N. J., on February 9. He was a veteran of the Civil War.

Dr. Gertrude H. Woodworth, a homeopathic physician of Chicago, died on February 9, at the age of sixty-five years. She was a graduate of the Hahnemann Medical College, Chicago, in 1897.

Dr. Chas. B. Leavitt died at Trenton, N. J., on February 9. He was a graduate of the University of Pennsylvania in the class of 1882.

Dr. Walter Pardee, one of the oldest homœopathic physicians in this city, died on February 11. He was born in Sharon, Conn., in 1822, but later removed to Rochester, N. Y. He was graduated from the Cleveland Medical College in 1860, coming to New York immediately afterward. He had a large practice, and for forty years lived in West Thirty-fourth street. He retired in 1882, and had since then been an invalid. He died at the home of his son, Dr. Ensign B. Pardee.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

CORONERS AND DOCTORS—FIRE AT A LUNATIC ASYLUM—LIVERPOOL TROPICAL SCHOOL—MR. SUTTON TIMMIS'S ENDOWMENT OF A CANCER RESEARCH—PROF. RONALD ROSS—DR. MANSON—OBITUARY NOTES.

LONDON, January 30, 1903.

IT is not often that a considerable proportion of the medical men in any locality can be got together to maintain their rights. Lately, however, about eighty residing in the southwest of the metropolis held a meeting to protest against the action of the coroner for the district in giving all autopsies to a single person. It seems, however, that the County Council is responsible for this. The Local Government Act of 1888 transferred to the county councils the right of appointing coroners. The London Council, which delights to have "a finger in every pie," has lately exacted from candidates for the appointments promises as to their future conduct—a course which has been pronounced by counsel illegal, as the rights transferred could not exceed those which previously existed. Among the promises extorted is one to entrust the post-mortem examinations to a skilled pathologist, except when satisfied that the medical man connected with the case is competent to make a trustworthy post mortem. This slur on the general practitioner is unworthy of a public body, to say nothing of the illegality of making such a condition.

In July, 1902, Mr. Troutbeck was appointed coroner for the southwest district, and has carried out the direction of the council with such persistence, and so little discretion, that an appeal is being made by a deputation of the local medical society to the council, and if that fails the matter will be brought before the Lord Chancellor.

Mr. Troutbeck "as wished by the council," has given nearly all post mortems to one Dr. Freyberger—a gentleman recommended and paid by the council. The fee for each post mortem is therefore diverted from the attendant practitioner, who must know most about the case. Dr. Freyberger's position is not easy to define. He appears at inquests as pathologist to the County Council, and describes himself as such in the Medical Directory, and yet the chairman of the council, challenged on the point, has publicly denied that any such appointment has been made. What then? Surely he would not admit that some "hole and corner" action had been taken by his fellow councillors without his cognizance. Whatever may be the explanation of these contradictions, some things come out clearly from the confusion. The council desired, by illegal pressure on coroners, to foist a public pathologist on the public, and in some mysterious method intimated to the coroners that Dr. Freyberger was their choice. I do not know much about his qualifications for the office, but everyone knows that this is not the way in which such an official should be appointed. The council in other cases has proceeded regularly, and I hear that in this instance some of the councillors feel aggrieved at the blunder which has been committed.

At the meeting of the Southwest Medical Society it was repeated again and again that the help of a pathologist would be welcomed in cases of difficulty, as much as that of the toxicologist or analyst is in cases of poisoning. But to allege that the general practitioner is not competent to make an ordinary post mortem and give evidence as to the cause of death is an insult to the mass of the profession.

But this does not seem to trouble Mr. Coroner Troutbeck, who is carrying out the council's behest with a high hand. In one case I am told he ordered a second examination by Dr. Freyberger after the pathologist of the hospital where the patient died had made an autopsy. In another case the practitioner who had been called in by the police and kept up artificial respiration for a long time was ignored, and Dr. Freyberger summoned to give evidence. Now, what help could he give to determine the cause of death, still less as to the circumstances attending the death, into both of which points it is the duty of the coroner to inquire?

Neither Mr. Troutbeck nor the council have occasion to be surprised that indignation should be produced by such a proceeding. But Mr. Troutbeck goes on his way disregarding opinions outside the council. Indeed, he seems specially deficient in tact. On Saturday he displayed considerable irritation at the result of one of his own actions. He told his jury he had written to the attendant doctor that he might come to the inquest as a witness, but had given the post mortem to Dr. Freyberger, and the doctor had replied in "a very impertinent letter protesting it was not the first time a doctor had been impertinent, but he was not going to call in gentlemen who had a prejudice to be judges in their own cases." Then he went on to instruct his jury that the feeding of the child was improper, and that he did not blame the parents. So the jury censured the doctor!

A coroner is in the position of a judge, and considers himself one. It is a pity, therefore, when such an official does not preserve the dignity and impartiality of a judicial functionary. Mr. Troutbeck's display of ill-temper seems likely to reawaken the contempt for "Crowner's 'quest law'" and procedure which was poured upon it by the great writer who flung at it that scornful phrase.

There is one thing which, perhaps, in fairness, should be stated: The performance of an autopsy is apt to interfere a good deal with a general practitioner's work, and a busy man is, therefore, often anxious to escape the duty. In a very serious case the demand on his time and attention may be unlimited. In a very simple case he may be tempted to carry it out in a perfunctory manner. But this, if an argument for the appointment of a special pathologist, is no excuse for shirking a duty when once it is undertaken.

Two or three times last year I mentioned incidents which were warnings of the ever-present danger of fire in hospitals. An awful object-lesson on this danger occurred early on Tuesday morning, when an annex of the Colney Hatch Lunatic Asylum was consumed in about half an hour, and fifty-two female patients perished in the flames. Such a catastrophe will, no doubt, have been cabled to your papers with many details. The disaster is without parallel in London. Its origin is at present unknown, but, perhaps, some light may be shed on it at the inquest, opened this afternoon.

The Colney Hatch asylum is under the control of the London County Council. The annex was built seven years ago by the Works Department, and cost £23,428, although the estimate was only £17,500. It was built of timber on brick foundations, lined inside with match-board and felt, outside with corrugated iron. How such materials could be permitted in view of the possibility of fire is asked on every side. Connected by a corridor there were five wards, each arranged for sixty patients. With nurses there were about 330 persons in the annex when the alarm was given, and it was not yet light. The difficulty of getting such a number of lunatics out of the building into a safe place is obvious; but it was met with British pluck and determination. The staff displayed the greatest energy and heroism. From the medical superintendent downward every doctor, nurse, attendant, and servant seemed to turn out on the sound of the alarm, and some of them suffered severe burns in their efforts. Even the firemen were loud in their praise of the gallant efforts of the staff.

This building was a "temporary" one, and was licensed as such in 1895 for five years; at the end of that period the license was renewed for another five years. Wanted—a definition of a temporary erection intended for the accommodation of closely-packed patients. The County Council for some time past has been compelling theaters to have the most elaborate precautions against the risk of fire. While so much in earnest for the protection of the public spending an evening in amusement, have councillors been equally anxious as to the building for helpless lunatics committed to their care for the whole day and night?

Kings College Hospital is expected to benefit under the will of the late Mr. Storks by an amount of about £60,000, and there is some talk of removing the hospital to another locality. It has for some time been remarked that too many of our hospitals are gathered together in the middle districts, and it is urged by many reformers that a better distribution over the metropolis is most desirable. This point is also urged in reference to Bart's, the committee on which was settled yesterday, and, I am glad to see, includes Sir Wm. Church, Prest., R.C.P., and Dr. Pye-Smith.

Liverpool is fortunate in her generous wealthy citizens. Mr. Sutton Timmis, who lately gave £10,000 to start a fund for cancer research there, responded to the appeal for the Children's Infirmary there, on the 22d, with a donation of £2,000. Dr. A. S. F. Grünbaum is to be the director of the research, and Sir W. Church said they could not have a better one. Last Saturday the dinner to Major Ronald Ross, F.R.S., was given by the Liverpool University College Association. The chairman, Sir Alfred Jones, said they might well be proud of what Professor Ross had done, and of their Tropical School, for the world was now copying Liverpool. Dr. Manson was present and congratulated the city on their wise activity, and wished all the kingdom would follow the example. He added that he was much impressed by the splendid buildings they had erected for research, though it was not so much buildings which were wanted, as men of ability and industry. The

best of Professor's Ross's work was done in a hut with a microscope, two needles, and a match-box.

Smallpox is still extending in the Midlands, chiefly among casuals in the work-houses.

Dr. Alex. Thomson, Consulting Surgeon to the Dumfries Infirmary, died on the 18th inst., aged seventy years, of acute pleurisy. He had not long recovered from an attack of influenza.

Dr. R. A. Campbell of Newcastle-on-Tyne died on the 21st inst., aged fifty-one years. He was one of the founders of the Newcastle Clinical Society, and was at one time on the staff of the Children's Hospital. But literature and art divided his love with medicine. He suffered from cardiac disease, and later from bronchitis

The will of Dr. David Little of Manchester has been proved for £99,711; Dr. S. Fenwick's will at £26,006.

LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

A GENERAL HOSPITAL FOR MANILA—A SANATORIUM AT BANGUED—EFFECTS OF THE CLIMATE UPON AMERICANS—CHOLERA—PLAGUE—SANITARY PROBLEMS—NEED OF DISPENSARIES AND HOSPITALS IN THE LARGER CITIES—NEW CHIEF OF THE GOVERNMENT LABORATORIES—MOSQUITOS OF THE PHILIPPINES.

MANILA, January 8, 1903.

A PETITION has just been presented to the Commission for the Philippines for the early establishment of a general hospital in Manila, an institution which is sorely needed at the present time. The petition was signed by about 3,000 of the most prominent Americans, Europeans, Filipinos, and Chinese in Manila, and was presented by the bishop of the Episcopal Church for the Philippines. The hospitals existing in Manila at present are totally insufficient as to number, capacity, and equipment. The new hospital is to have a capacity of 200 beds, and be built on the pavilion plan of light frame material. For the commencement of the work an appropriation of $65,000 is asked. The "Women's Hospital," established for the benefit of the white women in the islands, has lately been discontinued because of lack of funds. The construction of a large general hospital was begun some time since, but was discontinued because a clear title to the site occupied could not be secured. The skeleton framework of the hospital, on one of the best streets in Manila, is costly evidence of the lack of foresight of somebody in authority. There are several small private hospitals in Manila, but they, like the larger public Spanish hospitals, are not properly constructed and equipped, and can largely be disregarded in the consideration of the hospital needs of the city. The large army hospital, the First Reserve, with its 500 or more beds, is equipped in a thoroughly modern and complete way, and is administered by a large staff of surgeons, hospital corps men, and female nurses. Unfortunately for the large and increasing civilian element, the benefits of this hospital are reserved for those in the military service.

An excellent work is being done at Bangued, in the mountainous district of Northern Luzon, in the construction of a sanitarium to be used for the recuperation of Americans broken down by overwork and the depressing influences of the Manila climate. The work is being done under authority of the Civil Government, which has appropriated $200,000 for the construction of a road to make the sanitarium accessible, and open up commercially the Province of Bangued. Shortly before the cession of the Philippines to the United States, the Spanish had decided upon a sanitarium at this point, and had already constructed a large, substantial building for this purpose, which is now employed for administration purposes for the present hospital. No acute cases will be received at the new sanitarium, which will be kept more as a health resort for the broken-down than as a hospital, and which, it is hoped, will be to the Philippine Islands what Simla and the hill stations are to India, or Newcastle to the English in Jamaica. At present, a drawback to the Bangued sanitarium is its inaccessibility, it being forty miles from the nearest seaport, and reached only on horseback or by litters or sedan chairs carried by Igorrote carriers, who usually make the distance in about three days. Later, with the proposed extension of the Manila and Dagupan railway, Bangued will be reached from Manila by rail, with a much shorter distance over which ponies or carriers must be used than is at present required. The altitude of Bangued is about 6,000 feet, and the temperature is very equable the year round. The days are warm but never hot, while at night the thermometer always goes to 48°–50° F., and often lower, making warm wraps and open fires desirable. Pine trees predominate, and the usual tropical vegetation is left behind at a lower level. It is believed that nearly all the fruits and vegetables of the temperate zone can be readily raised at Bangued. The days are bright and clear until about four o'clock in the afternoon, when a heavy fog comes in from the sea, which renders the locality too damp for the best treatment of pulmonary tuberculosis. The night dews are very heavy. Water is abundant, pure, clear, and cold. There are excellent roads in the vicinity, and driving, riding, golf, tennis, and shooting will afford diversion. There is much game, such as deer, wild hogs, and wild chickens, in the neighborhood. The natives of the vicinity are Igorrotes, who are heathen, go about almost naked, and practise head hunting among themselves. They never responded to the civilizing influences of the Spaniards, and still remain savages of a most pronounced type.

It is expected that the new sanitarium will prove of great benefit to the white population of the Philippines, who now nearly all find it necessary to the maintenance of their health to visit the United States, Japan, or Europe every year or so. With the new sanitarium made accessible, it is thought that a sojourn of a month or so there will answer every purpose of a voyage to a colder climate, and will cost infinitely less in time and money expended. For white women and children, who especially do not well bear the hot and depressing climate of Manila and the seacoast, the opening up of the Bangued sanitarium will prove a great blessing and save the present necessity of seeking a frequent refuge in Japan.

There is no doubt but that American women and children, on the whole, do not do well, at least in Manila and the low-lying towns on the seacoast. It is true that there are occasional exceptions, but these emphasize the truth of the general rule. Particularly in the rainy season are the depressing influences of the climate manifested most rapidly, and it takes but a few months to convert a rosy, vivacious young woman into a pallid creature, lacking spirits and energy. It is almost possible to base a fair estimate of the length of an American woman's stay in the islands by her appearance. Menstrual disorders are the general rule. In most cases the periods are much lengthened, and there may be almost continuous flowing, causing such a drain on the system as to make the transfer of the woman to a cooler climate a necessity. Others have a partial or complete cessation of the menses, and drift into a nervous, irritable condition, trying to the sufferer and those around her. The latter class of cases is especially liable to be affected with partial loss of memory, a condition so common among the whites in the islands, both men and women, as to have its existence fully recognized, under the name of "Philippinitis," by the American colony. On the whole, men stand the climate far better than women, perhaps through the fact that duties call the former out of doors, and force them to take a certain amount of exercise. The women, however, usually stay in the house during the day *en deshabillé* and make their first public appearance in time for a drive on the Luneta about sunset, to return indoors for dinner and the social gayeties of the evening. It is no wonder that they soon look as pale and bleached as vegetation grown in the absence of sunlight. The men, on their part, drink too much, and the bad effects of too much alcohol are sooner manifested here than in more temperate climates. There is but little to amuse after business hours, and there is an ever-present desire for a long, cold, and wet drink of some kind or another—and, unfortunately, only few limit themselves to lemonade or carbonated waters. So far as the men are concerned, drinking seems to produce more bad results than the climate itself. Children at the breast stand the climate well; but if a child cannot be nursed by its mother, its condition is precarious, for fresh cow's milk of good quality is absolutely unattainable, and the Filipino woman does not seem to take very kindly to the position of wet nurse. Children from three to six or seven years old do well, provided they are carefully watched, and sterilized water and proper food are given. After about seven years old, ample experience shows that the child should be sent away until well after puberty, for girls begin to menstruate unduly early, with serious effect upon their health, development, and nervous tone, while both boys and girls constantly have sexual matters brought to their attention by the natives, who have neither modesty of language or person, and whose absolute lack of morals favors sexual precocity. For all these reasons, continued residence in the Philippines by Americans, with maintenance of health, is most difficult of accomplishment. In India it is said that the English race would die out in three generations were it not for the precautions taken and the constant infusion of fresh blood into the stock by immigration from England; and this rule can be laid down for the tropics, to which the Philippines are no exception. Even the Spaniards have never been able to colonize these islands successfully to the extent of performing manual work,

and it may be accepted that the white American is an exotic in the tropics, can only with difficulty maintain an existence therein, and that not for too long a time. This is a factor to which our legislators should give serious consideration, for it will seriously interfere with the Americanization of the Philippine Islands. We are too prone to forget this fact, and also to belittle the precautions which must be constantly observed in the maintenance of vital energy. Quite recently a battalion of our soldiers in Mindanao, operating against the Moros, was broken down by sickness as a result of the heavy labor which superior authority directed them to perform in the building of a military road. The British, in India, have learned the lesson of the conservation of vital energy, and go so far as to provide every cavalry soldier with a native helper to assist him in caring for his horse and equipment. It is folly to break down a costly soldier and ruin him for the purpose for which he was enlisted, by making him do manual labor in the tropics, which a native could be hired to do for a few cents a day.

The official figures for the cholera situation in the Philippine Islands, on January 5, 1903, gave a total of cases reported of 122,102, of deaths 77,323, and a mortality of 63 per cent. For the city of Manila the mortality has been reported as 75 per cent. The number of cases and deaths during the present epidemic having been distributed as follows:

	CASES.	DEATHS.
Filipinos	3,941	3,107
Chinese	340	179
Americans	150	76
Europeans	61	38
Others	36	19
TOTAL	4,548	3,419

These figures are correct as far as they go, but they do not go far enough. That is to say, that while the above figures are undoubtedly correct as representing cases of sickness and death from cholera, they by no means include all such cases which have occurred. The officials of the Sanitary Department are well aware of this fact, and do not hesitate to say that the gravity of the epidemic, except for the city of Manila, is by no means expressed in the returns received by them. The most conservative estimates of those best qualified to judge place the true number of cases of cholera at twice those actually reported, and the true number of deaths at about 80 per cent. more than appear in the official statistics. This raises the probable cholera mortality for the islands, from the inception of the present epidemic to January 5, 1903, to a total of 139,190 deaths, and the total number of cases to 244,204. Certainly the estimates should not be placed lower than this. Obviously, in the absence of reliable statistical data, it will be impossible to draw accurate scientific deductions from the history of the present cholera epidemic when it shall have been written.

One feature of the outbreak of cholera in the southern islands of the Philippines is the recrudescence of the old idea concerning the poisoning of wells in epidemics of this sort. This belief is firmly held by many Filipinos, who are convinced that the poisoning has been done by the Americans to bring about the extermination of the natives. In severe instances, American civil officials have been attacked for this reason by the ignorant natives of outlying villages, and sanitary work has been interfered with. The use of disinfectants, to which they are unaccustomed, is probably the reason for the present origination of this idea. That Kipling's description of the Oriental as "half devil and half child" is most applicable to the low-class Filipino, is almost daily demonstrated by such instances.

The Santiago Cholera Hospital, at Manila, was discontinued on January 1, after having been in existence since March 27, 1902, as the convent in which it was located will soon be reoccupied by the French Catholic sisters to whom it belongs. During the Filipino insurrection this convent was occupied by the military authorities for use as an army hospital. Since it became a cholera hospital, under the Civil Government, 1,268 cases of cholera have been treated therein, with an average mortality of 65.28 per cent. This number included 146 cases occurring in Americans, of which number 32.87 per cent. proved fatal. In the future all cholera cases outside those occurring in the military service will be treated in a Nipa hospital, of 200 beds' capacity, which has been erected on the grounds adjoining the San Lazaro leper and venereal hospital. The army maintains a separate cholera hospital for cases among soldiers. At present it contains no cases under treatment, but is kept in readiness for emergency.

Since the middle of December there have been no cases of cholera among the troops near Manila, and only a few cases among those in the southern islands, where the disease is now prevailing extensively. At the present writing, nine cases, with six deaths, are reported as having occurred in twenty-four hours in the garrison of a small one-company post on the island of Leyte. Such instances as this, however, are the rare exceptions which prove the thorough efficiency of the preventive measures generally employed by the army surgeons against cholera, and outbreaks of this sort can almost invariably be traced to disobedience of sanitary orders by soldiers. Example after example might be given where military garrisons escaped absolutely unscathed, while the pestilence was destroying 10 or 20 per cent. of the native population living around them and in close proximity. Cholera is readily amenable to control if proper sanitary regulations can be carried out; but, unfortunately, they cannot be properly carried out with the fatalistic Filipino.

Several cases of plague have recently appeared in Manila, apparently originating from a previously latent infection remaining after the outbreaks of the past two years. The cases all occurred in natives, and appeared in the districts largely populated by Chinese. Among all the cases which have occurred in the past, only one or two have occurred in Americans, and the great majority among Filipinos rather than Chinese. Nearly all have proved rapidly fatal. Although the highly insanitary habits and surroundings of the Chinese appear greatly to favor the continued existence of the infection, the fact that they wear much better protections for the feet and legs than do the Filipinos probably renders them much less liable to the occurrence of abrasions, through which the plague bacillus present in infected soil can gain entrance to the organism. This fact, and also the avoidance by them of the infected districts, can also explain the relative infrequency of the disease among the Americans. So far, plague seems to have manifested no special tendency to spread from Manila to the outlying towns or provinces, and to have been kept under by the efforts of the Manila health authorities, which have, however, been unable to eradicate the infection. The destruction of rats is being carried on by rat-catching crews of six Filipinos attached to every station of the Manila Board of Health, and is encouraged generally among the natives, although the bounty on rats was withdrawn during the temporary disappearance of plague during the past few months. Every effort is being made to improve the sanitary condition of the buildings in the infected districts, which are confined to the poorer quarters of Manila. As in Canton and other Chinese towns, the disease appears to have become endemic, and not readily to be stamped out, though its eradication from Hong Kong and Honolulu show what has been done under conditions which, while insanitary, were yet more favorable than those which exist in Manila at present.

As cholera seems to have escaped so wholly from control, the special efforts of the Manila health authorities seem to be now directed against the plague infection. The latter, however, appears to be very insidious and resistant, and will not soon be entirely destroyed without the use of the most stringent and expensive measures, which the health authorities are scarcely in a position, politically and financially, to apply at the present time. In fact, the question of ways and means is a most potent factor in the consideration of all sanitary problems in the Philippines, and often interferes to block sanitary progress.

Much laxity of method, and considerable dishonesty on the part of some of the officials, has been revealed by a recent investigation of the lately appointed Commissioner of Health into the affairs of his office. Financial matters have been found to be very much involved. The disbursing officer of the health service has been tried, convicted, and sentenced to twelve years in Bilibid Prison for embezzlement of funds, and several sanitary inspectors have been discharged for cause. It seems to be clear that many bribes have been taken from merchants, Chinese and others, though these facts have been so well concealed as to be difficult of legal proof. The power of discharge has, however, been unsparingly employed. It is very unfortunate that such malfeasance of office should have occurred, as this, while common enough under the Spanish administration of affairs, was not expected under American control. The fault seems to lie in the relatively untrustworthy and undesirable class of men who are now attracted by the small emoluments offered for service in the Board of Health. The remedy is a higher scale of pay and a corresponding elevation in the standard of morals and professional efficiency required. Medical men connected with the sanitary service should be well paid for their important work, and should not be permitted to engage in outside practice, which almost invariably results to the greater or less neglect of official duties. Examinations, under the Civil Service Commission, have been held in the United States for appointment as municipal and provincial health officers in the Philippines, and the names

of more than one hundred approved candidates are now on the waiting list available for appointment. The pay of such positions is to be $1,800 and $2,000 per annum, and the opportunity for outside practice figures among the inducements offered. This pay, however, is insufficient to secure the high class of medical men sorely needed by the health authorities, who are unwilling to undergo the discomforts and isolation incident to Philippine service for the sum offered. It would seem to be more advantageous to increase the above pay by 50 or even 100 per cent., and to reduce correspondingly the number of medical men employed. What is wanted by the health authorities is not a large number of general practitioners of medicine of mediocre ability, but a sufficiency of experts in sanitary matters, who are qualified to plan intelligently and supervise efficiently the execution of measures intimately connected with sanitary and financial welfare of large cities and whole provinces, counting their population by the hundred thousand. It would seem to the qualified observer that the Civil Government makes a serious mistake in placing quantity ahead of quality. General medical practitioners are settling in the islands in increasing numbers because of the opportunities for practice offered by the increasing American population in the large cities, but the sanitary experts of which there is most urgent need will never come to the Philippines except as Government officials and under a higher scale of pay than that now authorized.

An urgent need of the Philippine Islands at the present time also has to do with the establishment of dispensaries and hospitals in the larger cities at which indigent natives can receive free medical treatment of good character, also the districting of the provinces under qualified medical men, who should be required to treat gratuitously all patients not able to pay for treatment and living in their district. Of course, the hospitals and dispensaries would have to be supported, and the district physicians salaried, by the Civil Government. This system is employed by the British in many of their colonies, and works very successfully. At present the "rice-paddy" Filipino of the country is born, lives, and dies without ever receiving treatment by a qualified physician. He is too indolent to work, and, consequently, is unable to pay for the services of a medical man, who would not be able to exist in a small town, of even a couple of thousand inhabitants, without the aid of a salary from the Government. Where the average Filipino of the country earns and supports his family on about six dollars, United States currency, per month, it is idle to talk of his being able to pay living fees for medical attendance. As a result, large towns and provinces have not a single physician within their limits, and many deaths and disabilities occur which could readily be avoided by proper medical attention. Thus, on the island of Mindoro, a hundred miles long and fifty miles wide, only twelve hours' sail from Manila, there is not a single physician or drug store. A certain rude medical practice is attempted here and there by native "practicantes," but their knowledge is small, their practice empirical, and it is doubtful if their ministrations are not productive of more harm than good. Heroic doses of nauseous medicines of illy-understood effect are prescribed, and the application of blisters, as something which can be seen, felt, and appreciated by even the most ignorant "hombre" is a favorite method of treatment for any and every disease. Without even the most elementary knowledge of anatomy, surgery in any of its branches is quite beyond them, and, except in the treatment of fractures, is never attempted. Wounds received almost invariably go on to suppuration and are always serious—this probably explaining the disinclination of Filipinos to submit to any cutting operation. Antisepsis is not understood, and wounds are unhesitatingly infected by dirty fingers. Dressings carefully put on the wounds of natives by army surgeons are usually removed by "practicantes" subsequently having charge of the cases, and the wounds covered with dirty rags dipped in solutions of their own compounding. Operative midwifery is unknown, but, fortunately, the native women are blessed with easy deliveries as a general rule; when a serious complication occurs, they suffer and die without interference. This dearth of competent medical attendance, and its results, can scarcely be understood in the United States, when every little town or country crossroads has its doctor. There is no question but that the provision of hospitals, dispensaries, and government physicians is a most important part of the "white man's burden," which we have assumed in relation to the Philippines.

The resignation of Dr. Richard P. Strong, of his commission, as assistant surgeon, U. S. Army, has just been announced, he having accepted a place under the Civil Commission for the Philippine Islands as Chief of the new Government laboratories of Manila. With the resignation of Dr. Strong, the army loses one of its best young men, while the Civil Government could find no one better qualified to perform the duties of the place to which he has been appointed. Dr. Strong is a graduate of Yale and Johns Hopkins Universities, and of Johns Hopkins Hospital. He has been on duty in Manila for about three years, a large part of the time as the head of the Army Pathological Laboratory. He has carried on most valuable scientific work during his service, publishing exhaustive reports on the animal parasites of the Philippines and the etiology of the dysentery common in the islands. His serum for rinderpest is most successful in the immunization of animals against this disease, and is now being supplied gratuitously to all applicants by the Civil Government.

A careful study of the mosquitos to be found in the Philippine Archipelago is being made by the Army Medical Department. Surgeons at the various military stations are required to collect specimens of the various mosquitos found in the vicinity of their posts, and to forward them to the U. S. Army General Hospital at San Francisco, where they are examined and identified. Although to a certain extent entomological, it is thought that this work should have a close relation to the distribution and prevalence of certain diseases in the Philippine Islands. Already a new variety of Anopheles, probably malaria-bearing, has been identified as occurring among the mountainous region of Northern Luzon, while the mosquito most common in Manila and on the low-lying coast lands has been demonstrated to be the true Stegomyia, the intermediate host of the yellow-fever infection. Should the latter ever be carried to the Philippines; as may very likely occur after the completion of the Panama Canal, there is no question but that the disease would be spread rapidly, and prove most difficult, if not impossible, of control. Many of the medical men in the islands are also inclined to believe that some variety of mosquito serves as the transmitting agent of dengue fever, though this has not as yet been demonstrated.

In the present work of mosquito identification, collections are made at least monthly, and of as many varieties as are obtainable, so as to permit of a determination of the period of flight of each species at each collecting station, its relation to the seasons and to the prevalence of various fevers. It is thought that the data so secured will be suggestive of the species likely to give positive results for pathological study, and of the best methods and times for their destruction when this is practicable. Such identification and classification would also prevent the possible loss of time in looking for species, which, though known to be pathological, may not be present in the Philippines. By the systematic co-operation of the army surgeons, it is expected that reliable results can be obtained in a year or so, which, under ordinary conditions of mosquito collection and observation, would take many years to secure.

This is but one of the many tasks to which the Army Medical Department has set itself in the interests of medical progress, and the elevation of the sanitary condition of troops on duty in the tropics. The thoroughness with which it is being carried out augurs well for its success. That the army surgeons are making such good use of their unequaled opportunities for investigation into tropical diseases should be a cause for gratification and pride to the general medical profession of the country.

Two Cases of Suture of the Left Ventricle for Punctured and Incised Wounds.—Errico Giordano reports two cases of this operation. The first, a youth of twenty-three years, had received a dagger wound which penetrated into the myocardium. After suture the cardiac beats became stronger and more rhythmical, but the patient had lost so much blood that it was impossible to save his life, and he died of profound anæmia. The second patient was twenty-six years old, and in an attempt at suicide gave himself three knife wounds in the chest. One of the wounds had penetrated the myocardium of the left ventricle, where, from an incision two centimeters long, a gush of blood made its exit with every systole. Two stitches were introduced by means of a Madelung needle, the pericardium was sutured and the cutaneous wound closed with the exception of about one-fifth of its extent, in which a gauze was left for drainage. On the fourth day after the operation the temperature rose, and examination showed that one of the wounds had not healed, but that there was a focus of pus. This was emptied and drained, and the temperature in two days fell to normal. The deeper part of the wound united, but a portion of the superficial wound showed no tendency to cicatrization, and at one extremity became necrotic; the author therefore scraped the granulating surfaces and removed the necrosed portions. A complete recovery followed.—*Giornale Internazionale delle Scienze Mediche*, January 15, 1903.

Progress of Medical Science.

The Boston Medical and Surgical Journal, Feb. 12, 1903.

A Form of Pressure Anæmia of the Uvula Which May Be Mistaken for Membrane.—W. P. Coues says that this condition of the uvula has come to his notice in several cases of severe throat infection when the tonsils have become greatly swollen, so that one or both impinge on the side of the uvula, almost blocking up the throat. On gently separating the tonsil from the uvula a white spot is seen, which may, in a hasty examination, particularly if diphtheria is suspected, be mistaken for membrane. Continued pressure of the tonsil on this spot may even cut off the circulation of that part of the uvula and lead to a superficial necrosis. On more careful examination it will be seen that the white spot is formed at exactly the point of impact of the tonsil and uvula, that it is not raised above the surface, and that it does not bleed when touched. This condition, the author believes, occurs usually in streptococcus infection of the throat, when a non-diphtheritic membrane is perfectly possible.

A Report of a Case of Multiple Neuritis of Questionable Origin.—Arthur W. Marsh and George C. Smith report the case of a patient who was suffering from a slight attack of pharyngitis. This was followed by a period of about two weeks of general weakness with freedom from pain, during which time there was also great nervousness. Then came seven weeks of pain, with swelling and tenderness in all four extremities. During this time hallucinations of sight, sound, location, and fright were present. This period was followed by a month of freedom from pain, but by steadily increasing cloudiness of the mental faculties. Finally a period of four to five days of very high fever, terminating in death. It was evident that the patient had a multiple neuritis, and that it was merely an expression of, or sequel to, an acute infection of some kind which had existed some time before peripheral neuritis manifested itself. Other causes being excluded, the two acute infections which suggested themselves as the most probable were influenza and tuberculosis. The authors give the various arguments in favor of and against each of these conditions and leave the question of etiology undecided.

Journal of the American Medical Association, Feb. 14, 1903.

A Study of the Contents of the Vesicles and Pustules of Smallpox.—J. F. Schamberg has studied cultures from eighty-two lesions in fifty-one different patients He concludes that the pustulation in smallpox is not due to secondary infection with any of the ordinary pyogenic germs, but is the result, in all probability, of the action of the microorganism which produces the disease. Streptococci and other adventitious bacteria may be present in the late pustules, but occur only exceptionally in the early lesions. It is probable that the streptococcus plays an important part in the development of impetigo, boils, abscesses, erysipelas, and gangrene which so commonly complicate smallpox.

Sanitation and Politics.—Walter Wyman says that it would make an interesting chapter to detail the interference of faulty politics with sanitary affairs. Everyone will recall instances of the shameful sacrifice of sanitary and health matters to the selfish and unrighteous interests of unworthy politicians, but the simple inveighing against unprincipled politicians and impure politics has no corrective tendency. A more effective way is by substitution, by forcing to the front worthy issues on which the best citizens and worthy politicians may unite, and it has frequently occurred to me that such issues may be found in sanitary and hygienic policies. Thus can politics be made to aid us in hygienic and sanitary reforms and in the attainment of that sanitary welfare of communities and nations which means fresh air and sunlight, pure water and house drainage, sewerage and good paving, for the enjoyment of all. These the rich already possess, but the poor do not. But the rich cannot reap the full benefits of these possessions until they are shared in by the poor, for the diseases incident to the overcrowding and bad sanitation of the homes of the poor find their way into the homes of the wealthy.

Medical News February 14, 1903.

Postdiphtheritic Paralysis Affecting the Ear and Throat.—Carle Lee Felt states that the most frequent site of the paralysis is the pharynx. The ear may suffer and deafness result. The duration of these palsies may be from a few days to weeks or months, and, rarely, may never be recovered from. The restoration of function depends first upon the nature and extent of damage done, and, when the damage is reparable, upon the treatment and care of the case. It is generally conceded that antitoxin prevents and never causes paralysis. Rest in bed, nutritious and easily assimilable diet, the perfect action of skin, kidneys, and bowels, are all adjuvants in lessening the severity of the paralysis. Strychnine is the most useful drug to restore impaired function. Electricity, tonic baths, and general massage are all beneficial.

Postdiphtheritic Paralysis Affecting the General Nervous System.—Luther C. Peter believes that the frequency of paralysis is in direct proportion to the severity of the general infection, although a severe form of palsy may follow a mild type of diphtheritic intoxication. Diphtheria of the posterior nares predisposes especially to both local and widespread palsy. The most generally accepted view of the pathology of this affection is that the entire neuron, either motor or sensory, may be the seat of pathological changes, the peripheral neuritis predominating and often existing without demonstrable change in the cord. The most characteristic symptoms of onset are irregular heart action, bradycardia, tachycardia, a lowering of temperature and vomiting. Diagnosis offers little difficulty. The prognosis in general is good. The use of antitoxin is a valuable prophylactic against paralysis. Absolute rest is imperative even for several days after the external evidences of the disease have disappeared. Iron and strychnine in liberal doses are probably the most satisfactory drugs.

Postdiphtheritic Ocular Paralysis.—P. N. K. Schwenk declares that of all acute infectious diseases, diphtheria is the most common cause of ocular paralysis. This paralysis is an essential part of the disease, probably due to its toxins. Generally the paralysis appears first in the fauces, affecting deglutition and then involving successively the muscles of accommodation and those of the extremities. Two striking points are: Only a comparatively small number of muscles are usually affected at the same time; the sphincter muscles are seldom or almost never involved in the paresis. The ciliary muscles are more often involved as a sequence of diphtheria than any other part of the muscular system, excepting the velum palati. Diphtheritic paralysis is generally bilateral. The paralysis of accommodation shows itself in from two to six weeks after an attack of diphtheria, and generally passes off in about the same time. Recovery is more rapid in the young than in the old. The affection is noted in convalescence in the inability to see near objects acutely. Diplopia is observed when one or more of the extrinsic muscles are affected. The affection of the external muscles is generally of short duration, except when the two internal recti muscles are involved. The peripheral theory alone will account for the generally active pupils, the frequency of paresis rather than paralysis, and the bilateral character of the lesions.

New York Medical Journal, February 14, 1903.

Residual Urine.—H. E. Hale says that one cause of residual urine may be the hypertrophied middle lobe of the prostate, behind the internal orifice of the urethra. Thus the internal aspect of the base of the bladder is divided by a transverse dam into an anterior and posterior pocket. The former is drained by the urethra, while the latter is not so drained in the upright position. When such a condition is found the patient is directed to void his urine twice daily while in the knee-elbow position. Patients in whom the bladder wall has lost its tonicity are not benefited by this method of urinating; its sphere of usefulness is limited to the earlier stages of disease.

The Etiological Significance of Heberden's Nodes.—Under this title E. M. Merrins refers to the little hard knobs about the size of a pea frequenty seen upon the fingers, particularly a little below the top, near the point. They are due to an osteophytic enlargement of the tubercles of bone normally present on the bases of the phalanges, the second row sometimes being affected as well as the third; the morbid changes in the adjacent joint structures are indistinguishable from those of osteoarthritis, and the cystic swellings often seen upon the summit of the nodes are protrusions of the synovial membrane. Peculiar sensations, such as numbness and pricking, often accompany their development, and in some cases there is pain, though this is seldom severe. They may exist as isolated phenomena, but are generally associated with affections of other joints. These nodules have been variously interpreted as characteristic of gout, cancer, autointoxication, senility, rheumatoid arthritis, wear and tear of various occupations, and certain cases of Raynaud's disease. In nearly all of these there is some mechanical, chemical, or toxic irritant in the system. Vitality is impaired, and finally we know that any abnormity of the circulation due to vasomotor disturbance, arteriosclerosis, or other cause, interferes with the nutrition of the tissues, and this bears most heavily upon the extremities, because they are peripheral and so at a dis-

advantage as regards the influence of cold and their supply of blood. Heberden's nodes, then, are simply evidences of structural degeneration dependent upon one or more of the factors above mentioned, and may occur in any condition in which such factors are present; but they are most likely to occur in those chronic diseases in which morbid bony changes form the principal feature of the disease, as in gout and the osteoarthritic variety of rheumatoid disease.

American Medicine, February 14, 1903.

The Nervous Cardiac Symptoms Due to High Altitudes.—F. Savary Pearce considers first the effect of altitude upon the heart in normal people. When not made suddenly, and to a height not greater than 5,280 feet, changes of altitudes in healthful countries will not cause the least disturbance. Increasing altitude tends to produce a more easily excitable heart in normal persons, due partly to the increased peripheral circulation through the lessened vis-a-fronte. If this is continued through several generations, dwarfism may result as in the men of Thibet. Next is considered the effect of altitude upon the heart in functional nervous disease. The "nervous heart" is entirely dependent upon the nervous system. The rapid, irritable heart is frequent in neurasthenics. It is well-known that an altitude of over 2,000 feet is contra-indicated for the neurasthenic or convalescent. Neither should he be exposed to high winds or frequent fogs. A sea voyage is generally beneficial. If it is not stormy it is soothing, both physically and psychically. In case of organic disease of the nervous system any change of altitude should be considered very carefully in relation to the rhythm of the heart, absence of cardiac disease, etc. The writer believes that altitude will have a favorable effect on the heart in cases of hypertrophy when due to resistance in the course of the circulation peripheral to the capillaries, as in Raynaud's disease and angioneurotic œdema. Moderate altitude is demanded in disease of the endocardium. In cases of loss of compensation, an altitude of 2,500 feet or more in a dry climate will be beneficial in most cases. Emphysema, especially if associated with asthma, will often be benefited by a high dry altitude.

The Significance of the Presence of Streptococci in Market Milk.—Raymond Clinton Reed states that their is great confusion in the study of streptococci. Their classification is still unsettled. The common prevalence of mammitis in the cow constitutes an important source of streptococci in market milk. The insidious onset of the disease is responsible to some degree for the marketing of infected milk by dealers with innocent intentions. The milk, directly after drawing, is usually strained into a forty-quart can, or even larger receptacle. The existence of udder inflammation is frequently first brought to notice by curd-like masses lodged on the strainer after the infected milk has been mixed with the wholesome milk. The ignorance or greed of the milker, or both, may prevent the rejection of the infected lot. From the references available to us, it is evident that the medical profession regards the presence of streptococci in market milk as dangerous to public health. The transition from the condition in which a few streptococci remain after a mild attack of mammitis to one in which streptococci are found in a healthy udder is a slight one. The writer adds that he has been unable to discover characters by which the streptococci found in the healthy udder can be differentiated from those associated with active inflammation of that gland. Recent investigations indicate that streptococci are found in the healthy udder more frequently than was formerly believed to be the case. In order to understand the conditions under which these streptococci harbored in the healthy udder may become virulent will require a further study of the pathology of mammitis.

Philadelphia Medical Journal, February 7, 1903.

A Study of Fifty-five Fatal Cases of Pertussis.—Marion McH. Hull concludes his paper as follows: The indications are plainly to support the patient, to establish an equilibrium in the nerve centers, and to prevent the further absorption of toxins by destroying the microorganism producing them. The first indication is best met by plenty of fresh air and digestible, nourishing food; by stimulants carefully used; by iron in a form that will not derange the digestion, and by quinine, given with the same precaution. No drug should be used that interferes with the processes of digestion and assimilation in a disease that calls for so much of the patient's vital force. The second indication is best met by the measures just mentioned, and by nerve sedatives. The third indication is best met by antiseptic sprays, difficult as they are to use with the class of sufferers under consideration. The writer believes that the characteristic lesion of the disease is a bronchial catarrh, caused by the specific microorganism, the toxin of which acts principally on the nerve centers, lowering their resistance to afferent impulses of all kinds: those centers controlling the respiratory tract, and especially that of the superior laryngeal nerve, being more affected than the others.

The Elevation of the Stomach in Gastroptosis by the Surgical Plication of the Gastrohepatic and Gastrophrenic Ligaments; an Original Operation.—Henry D. Beyea describes his operation: The abdomen is opened midway between the xiphoid cartilage and umbilicus. The tissues are separated and the peritoneal cavity opened, exposing a small portion of the lesser curvature and cardiac end of the stomach, the gastrohepatic ligament or omentum, gostrophrenic ligament and the lower portion of the left lobe of the liver. The table is elevated to the Trendelenburg position, and the stomach displaced still further downward and out of the wound by means of gauze sponges. This slightly stretches and separates from the underlying structures, the gastrohepatic and gastrophrenic ligaments, which permits an accurate determination of their length, and facilitates operation. The principle of this operation is that, by placing three rows of interrrupted silk sutures from above downward and from right to left through the gastrophrenic and gastrohepatic ligaments, a broad transverse fold or plication is formed in shortening these ligamentary supports and elevating the stomach to normal position. The normal ligaments are shortened and the stomach elevated to position without disturbing the physiological mobility or functions of the organ. The suturing is strictly confined to the normal ligamentary supports, and the distance between the rows from left to right is increased with the length of the ligaments, being greater toward the right. The sutures are secured, and the stomach, particularly the pyloric end, is elevated to a little above the normal position. The results of this operation have been wonderfully encouraging.

Philadelphia Medical Journal, February 14, 1903.

The Röntgen Treatment of Malignant Disease.—Charles Lester Leonard says that the best method of treatment seems to be the combination of early radical surgical operation and the Röntgen treatment. The curative power of the Röntgen treatment is not uniform. Its action appears to be both stimulant and alterative. The dosage or amount of alterative agent best adapted to different varieties of tumors has not been determined. This agent has an alterative and destructive action upon malignant tissue, producing retrograde changes that vary in their degree and intensity. When the dosage shall be determined, this agent will undoubtedly prove to be one of the most potent. As a primary method of treatment it has no place, except when operation is contraindicated or when more cosmetic results can be produced, in cases which life is not threatened by delay or in which the disease is already inoperable. This agent must be employed with great care.

Immunization against Tuberculosis.—Simon Flexner reviews the work done on this subject. He states that perhaps the most conclusive experiments have been made by Pearson and Gilliland. These workers, by using suspensions of cultures of human bacilli for inoculation of healthy cattle, have succeeded in affording a protection almost absolute for bovine bacilli, otherwise virulent for these animals. After repeated intravenous injections of cultures of tubercle bacilli from human sputum, the resistance of young cattle to virulent tubercle bacilli of bovine origin may be increased to such an extent that they are not injured by inoculations with quantities of the latter bacilli sufficient to cause extensive tuberculous disease, or to produce death in animals not so protected. It is an unprofitable attitude to assume longer any generic distinction between bovine and human bacilli. The successful attempts to produce immunity from bovine tuberculosis do not stand out as isolated performances, but are merely the ultimata of many unsuccessful and some partly successful experiments which have gone before. Theobald Smith demonstrated the differences between bovine and human tubercle bacilli. Trudeau protected rabbits and guinea-pigs from certain tuberculous infections by previous inoculation with tubercle bacilli of diminished virulence. It is a matter of national pride that both of these investigators are Americans.

Tropical Diseases.—Charles F. Kieffer discusses four diseases very closely allied to dysentery: epidemic gangrenous rectitis; chronic rectitis; hill diarrhœa; sprue psilosis or atrophic enteritis. Epidemic gangrenous rectitis begins with local symptoms referred to the anus and lower rectum. There is burning and intolerable itching, followed by severe dysenteric symptoms. The etiology is quite obscure. This disease is an expression

of a localized dysenteric process rather than a separate morbid entity. Treatment consists in antisepsis of the rectum with creolin or hydrogen peroxide, adding opium to the local treatment for the relief of pain. In prolapse of the rectum it should be covered with freshly ignited charcoal. The disease is very fatal. Chronic rectitis is a slow inflammatory process in the rectum which seems to follow dysentery, but may occur without it. The sphincter should be widely divulsed and a tube wrapped with iodoform gauze inserted and retained several days. In hill diarrhœa the dyspeptic symptoms are quite pronounced. Little is known of the pathology of this peculiar condition. The diarrhœa comes on generally in the early morning, continues during the forenoon and ceases about midday. Treatment is directed to the restoration of intestinal digestion and the maintenance of a relative degree of rest to the tract by liquid or milk diet. Sprue is not a distinct morbid entity. Clinically, it presents three cardinal symptoms: sore mouth, flatulency, and diarrhœa. Its course is very slow and chronic. If treatment is begun before the atrophy of the bowel is too far advanced, cure is the rule. There should be an absolute milk diet, which should be taken slowly. The quantity is gradually increased till the patient can take a gallon of milk a day. This must be continued for from four to six weeks, and then, very gradually, soft diet is resumed and in the course of months, with extreme care, mixed diet may be assimilated.

The Lancet, January 31, 1903.

Suppression of Urine in a Case of Ovarian Tumor and Pregnancy; Removal of Tumor and Uterus; Recovery.—B. Pitts gives in detail the history of a case of the nature suggested by the title. He notes that the anuria of pregnancy practically occurs only under two conditions: (1) when pregnancy is associated with definite acute nephritis and (2) in eclampsia arising from definite renal lesions. In both of these we look for general œdema, headache, vomiting, tremors, and general convulsions (the symptom complex present in his own case). Pressure, as of a tumor on the sympathetic flexus, does not explain anuria. Traumatism by its influence through the sympathetic system may produce oliguria or anuria, but it is hardly conceivable that a steadily-increasing pressure on the sympathetic should produce so serious an effect on the action of the kidneys without the addition of some additional factor as catheterization or the movement of a calculus.

Sunstroke.—After describing a fatal case, J. G. Duncanson says that the solar rays act, in the first place, directly by causing a disturbance in those vasomotor centers which are situated in the medulla, affecting the proper discharge of their functions, and specially interfering with the action of the sympathetic system. The blood vessels of the brain are enormously dilated, also those of the cord and the thoracic and abdominal organs; but those throughout the voluntary muscular system do not appear to be affected. The contracted pupils, absence of sweat, Cheyne-Stokes' respiration, and hyperpyrexia, all primary symptoms, point to this conclusion. It is not possible that a microbic influence is at work, and the early appearance of leptomeningitis would tend to give support to this theory. For treatment Duncanson advocates the usual cold baths, calomel purgation, and the frequent use of combination of spirit of Minderérus, bromide of potassium, and sweet spirit of niter. Digitalis and stimulants are called for by a flagging circulation. Strychnine is not indicated.

The Meaning of Uric Acid and the Urates.—Woods-Hutchinson says: (1) There is no connection whatever between the production of urea and of uric acid, hence interdiction and marked limitation of animal or of nitrogenous foods, as such, in gout is irrational. (2) The uric acid produced in health comes exclusively from two sources, the larger moiety, or *exogenous* uric acid of Chittenden, from the nucleins and purin bases of the food, the smaller, or *endogenous* moiety, from the destructive metabolism of the nucleins of the body tissues. (3) It is the *endogenous moiety alone* which is increased in gout and lithæmia. (4) Gout and lithæmia are mere symptom names for a miscellaneous group of chronic toxæmic processes of widely varied origin, characterized by the production of uric acid and the urates. (5) By "gouty diathesis" we mean the possession of a sufficient degree of resisting power on the part of the protective cells of the body to oppose the entrance of any poison, whatever its character or source, with consequent destructive metabolism and production of uric acid, but not adequate to neutralize or successfully to prevent its absorption. (6) The uric acid of gout, like the phosphoric acid which invariably accompanies it, is merely a result and measure of the destructive metabolism of the nucleins of the body cells, chiefly probably of the leucocytes, in response to the invasion of poisons or toxins, either organic or inorganic (lead, phosphorus, alcohol, acetone). (7) Hence the use of lithia or other "solvent" agents is irrational, and any benefits resulting are to be explained on other grounds. (8) As most of the toxins setting up this destructive metabolism and consequent uric acid production are of intestinal origin or entry, *diet in gout should be regulated solely with regard to the diminution of intestinal fermentation and putrefaction.* (9) As animal foods, from their much more appetizing and attractive flavors, are more apt to be indulged in in excess of the oxidative powers of the body, their limitation may be found to be more frequently necessary than that of vegetable foods, but sugars and starches are also very often at fault. (10) As uric acid and the alloxur group are not toxic, or at best feebly so, and are not the cause of gout, the prohibition of even foods rich in nucleins and purin bases, such as red meats, roe, and sweetbreads, has no rational basis, and is clinically of doubtful utility, except by diminishing the attractiveness of the dietary. (11) The rôle of the liver in gout is a negative one, being inability to perform its chief normal function as a "poison filter," and to absorb or to transform into harmless excretory substances the excess of toxins brought to it by the portal vein. (12) The drugs found of value in gout owe their efficacy chiefly to their power of checking intestinal putrefaction or of preventing the absorption or promoting the elimination of its products.

The Lancet, February 7, 1903.

A Case of Spurious Labor.—The patient of J. A. A. Pereiva was a woman of twenty-four years. Exactly nine months after her marriage he was sent for, the message stating that the patient was in labor. On his arrival at the house, he found labor apparently in full progress; the patient in bed with her face in the pillow and pulling vigorously at a jack-towel tied to the foot of the bed. Examination, however, revealed a flat abdomen and a hard conical cervix. The patient belonged to a very neurotic family.

The Infective Nature and Etiology of Pernicious Anæmia.—W. Hunter regards this disease as identical with the "idiopathic anæmia" of Addison. Of twenty-five cases observed by him during three years the age varied from thirty-two to seventy-two years; nineteen were men and six were women; seventeen were private and eight were hospital patients. A history of antecedent gastric or intestinal disturbance was found in every case, but in none were the disturbance sufficient to account for the profound anæmia. In all the foregoing and in the cases (seven in number) in which autopsies were made, there were invariably present infective lesions in the mouth, tongue, stomach, or intestine, either singly or associated with each other. These were of two classes: (1) A special form of glossitis (in every case); (2) septic lesions—viz., (*a*) a preceding or existing "oral sepsis" (twenty-four cases); (*b*) "septic gastritis," the condition previously described, as a common result of long-continued oral sepsis, causing finally gastric atrophy (more or less in every case and most intense in three cases); and (*c*) "septic enteritis," *e. g.* a croupous enteritis, patches of congestion and catarrh, follicular enlargement, and patchy colitis (three cases). Yet none of these were, in the author's opinion, the true cause of the condition. From all these facts Hunter concludes that the malady is due to some special etiology—general etiology will not account for it. The two classes of lesions he considers of importance are a special hæmolysis and a glossitis. The former is characterized by an excess of iron in the liver, spleen, and kidneys. Hence there are two sets of infective factors: (1) A specific hæmolytic infection, whose site and lesions are as above noted, and (2) a septic infection arising from some portion of the gastroenteric tract and probably in the tongue.

British Medical Journal, January 31, 1903.

On a Case Illustrating the Value of Physiological Rest.—W. M. Willis reports the case of a man seventy-two years old who suffered from pain in the rectum and the passage of large quantities of pus and blood. A large ulcerating surface was found on the posterior wall of the rectum, and extending around the greater part of the circumference of the bowel and reaching down to about two inches from the anus. Malignant disease was excluded from the fact that there was an absence of extreme induration of the edges of the ulcer. His age, and the acuteness of the trouble, rendered tubercle improbable. His sex and the characters of the ulcer were not in favor of syphilis. It was inflammatory in nature, but the cause was not apparent. The virulence of the inflammation, as shown by a large slough, suggested an acute septic process. Colotomy was performed in two stages. For about a

week after the colon was opened, the rectum was washed through once daily, and on several occasions one ounce of iodoform emulsion was thrown into it after the irrigation. In less than a month all the ulceration was healed. Later the colotomy wound was closed. The disease was cured solely by the application of "physiological rest" to the part.

Case of Puerperal Hyperpyrexia of Malarial Origin.—Thomas William Clay reports the case of a primipara of twenty-eight years whom he delivered. On the seventh day the patient was taken with a severe chill, after which her temperature rose to 102.4° F. An enema was given and a large motion passed. Three hours from the onset of the first rigor a second severe chill came on. The temperature then rose to 107.8° F. Ice was applied to the head and rubbed on the skin of the abdomen and thorax. The temperature began to fall. Quinine was given, and the temperature became normal in four days. About one and a half years later the patient gave birth to a second child, and again on the twelfth day she had an attack resembling that after the first confinement. Quinine was administered and the temperature was normal in twenty-four hours. The main points in diagnosis of malarial puerperal fever from puerperal septicæmia as seen in this case are: The onset of fever did not take place until after the fifth day, probably always before this in septicæmia. The well-marked rigors and intermission of temperature were far more pronounced than in septicæmia. The duration of the symptoms was short.

British Medical Journal, February 7, 1903.

The Effects of Vaccinating During a Menstrual Period.—H. E. Rumley Dawson describes this unusual case. The patient, a woman of twenty-nine years, was vaccinated on the second day of her menstrual period. She fainted at the operation. The flow stopped completely and did not return. Her ordinary period was six days. The vaccination locally was a success. There was practical cessation of menstruation with symptoms of a premature menopause. Five months after the vaccination she vomited two full pints of very dark-looking blood, and gastric ulcer was diagnosed. That day the menstrual flow came on profusely, and lasted for six days. The diagnosis of gastric ulcer was later questioned, for she has been in good health since this period, with regular menstruation, and just after the attack of vomiting she journeyed to her home and stood the trip well. The hæmatemesis was then looked upon as due not to an ulcer, but as symptomatic of incipient menstruation. The case certainly indicates that it is not advisable to vaccinate at or during a menstrual period except under circumstances of great emergency.

On the Bilberry (Vaccinium Myrtillus) as a Remedy in Typhoid Fever and Other Infectious Diseases of the Intestine.—Max M. Bernstein has made a series of laboratory tests which show that the typhoid bacillus, Gaertner's bacillus, the cholera vibrio, and one kind of the pathogenic species of the bacillus coli communis were killed by the neutralized decoction of bilberry within twenty-four hours, whilst another kind of pathogenic bacillus coli was inhibited in its growth for twenty-four hours, and only the laboratory type (probably non-pathogenic) retained its vitality unimpaired. Stronger preparations would, of course, have a still prompter action. The strength need not be limited, as the berries are not poisonous. The infusion on the jam has a pleasant, fragrant, and refreshing taste. It can be taken hot or cold, and it can be easily mixed with mineral waters, tea, milk, etc. Neither the acid juice of the stomach nor the alkaline contents of the bowels will interfere with the action of the drug which reaches down to the correct part of the bowel. In enteric fever, V. myrtillus can claim to keep the intestine aseptic as far as bacillus typhosus is concerned, to prevent reabsorption and reinfection, and so prevent and cut short the duration of the infection. Its astringent and antibacillary effects act in a soothing, cleansing, and healing manner. The writer also believes that the antifermentative action of myrtillus will be of great use in avoiding perforation by preventing flatulence, which raises the intestinal pressure.

A Clinical Lecture on Astereognosis in Tabes Dorsalis.—George E. Renne declares that to arrive at an accurate judgment, or, in other words, for the complete normality of the stereognostic sense, it is clear that the cerebral cortical center or centers, the conducting paths, and the peripheral receptive sensory mechanisms must be intact. Disturbance of either of these parts of the nervous system may lead to the manifestation of "astereognosis." By clinical investigation it has been proved pretty conclusively that astereognosis may be present in a complete form in disease of the superior parietal lobe of the brain. Thus it may be assumed that this part of the cerebral cortex is concerned in the coördination or elaboration of the special sensations received from the periphery. The special sensations concerned in the recognition of the physical characters of objects felt with the eyes closed are as follows: The spacing sense; the localizing sense; the muscular sense, and sense of posture; pressure sense; temperature sense; pain sense. The loss of one or more of these different "senses" may determine an error of judgment, or an entire loss of this faculty. The writer reports two cases of tabes with the loss of the stereognostic sense. There is not the smallest evidence of any cerebral cortical disease such as would lead to the defective coördination of sensory impressions received from the periphery; thus it must be that the dissociation takes place either in the spinal cord from defective conduction, or in the peripheral sensory receptive mechanism. When astereognosis occurs in tabes, it is a manifestation of dissociation of these special sensory perceptions, which normally are all coördinated in the higher sensory centers in the brain. It does not occur in every case of tabes, which also goes to show the random action of the toxin, which, while it affects the afferent sensory neuron as a whole, in different cases, appears to affect more particularly different peripheral sensory structures or afferent nerve fibers.

Münchener medicinische Wochenschrift, January 20, 1903.

Trachoma.—A. Peters emphasizes the fact that trachoma is not to be diagnosed solely by the presence of the granules. There is no doubt but that many cases of true trachoma never show any granules. The observation of several epidemics have conclusively proven this. Frequently cases have been observed which cannot be differentiated on symptoms from ordinary chronic conjunctivitis. These cases, however, are contagious, and the contagium may give rise to the formation of true granules in other persons. In the prophylaxis of the disease these cases deserve most careful consideration, since their causative relation to the spread of the disease has been amply proven.

The Employment of Boracic Acid in Internal Medicine.—G. Merkel shows that the internal administration of boracic acid is injurious, in that it attacks the mucous membrane of the intestinal tract and thus gives rise to pronounced disturbances of the same. Eleven persons suffering from different diseases were given boracic acid by the stomach. The usual dose was 2 g. per day in watery solution. The longest period of administration was eight and the shortest two days. In all but four of these persons disturbances of the intestinal tract appeared shortly after beginning the treatment. The chief symptoms were gas formation in the stomach or intestines, marked pains in the same and diarrhœa. The author has had no experience with the administration of this drug to healthy persons, but does not regard this as essential to an opinion, since all of the above eleven persons showed no intestinal or gastric symptoms before taking the boracic acid. It seems certain that this substance causes gastrointestinal disturbances when employed internally, in the majority of cases, and should, if given at all, be used with great caution. It should never be used as a preservative for the various canned foods. Foods prepared with it should never be given to sick persons, nor even to those who are healthy, in any considerable quantity.

Deutsche medicinische Wochenschrift, January 22, 1903.

Differentiation of Human from Animal Bones by Wassermann's Method.—Albert Schütze has investigated, experimentally, this method. The principal of the method consists in the precipitation of human albuminoids by a specific antiserum—that is, a serum obtained from animals which have been subjected to consecutive inoculations of human albuminoids will precipitate such albuminoids in given dilution, but will have no such action against albuminoids of animal derivation. Schütze shows that the success of the method largely depends upon the nature and condition of the bones to be differentiated; thus fresh bones, rich in albuminous matter, are easily identified, while much more difficulty is experienced with bones which are dried or are poor in albuminoids. All in all, it may be said that under proper limitations the method is of value, and may be regarded as of a certain definite value in forensic medicine.

Free Receptors of Typhoid and Dysentery Bacilli and Dysentery Toxin.—M. Neisser and K. Shiga show, by a series of experiments, that certain receptors of typhoid and dysentery bacilli are free and easily pass into solutions which contain such organisms. Such receptors may be found in a mixture obtained as follows: a 24-hr. agar culture of one of the organisms is emulsified in 10 c.c. of sterile physiological saline solution and heated for 1 hr. at 60° C. It is then incubated for two days at 37° C, and filtered

through a porcelain filter. This fluid markedly accelerates the action of its corresponding immune serum, and when inoculated into rabbits gives rise to an agglutinating and bactericidal serum of very high power. If the above mixture is prepared with dysentery bacilli it contains a powerful toxin identical with that first described by Conradi. If 5 c.c. or 2 c.c. of the mixture is inoculated intravenously into rabbits they die within forty-eight hours and show the characteristic autopsy findings of dysentery. The action of this toxin is greatly weakened if in its preparation 75° C. instead of 60° C. is employed. It is precipitated by alcohol or ether, but is not deteriorated thereby.

Causation of Carcinoma.—L. Feinberg defends his recently described organism against the attacks of Hertwig, Lubarsch, and others. The chief facts which show that these bodies are parasites and not degenerative or other products of carcinomatus tissue relate to their histological structure. It is a well-known fact that the composite cells of animals or plants show a well-defined nuclear structure and one or more nucleoli, while single-celled microorganisms show neither of these. These latter, however, possess a nuclear substance, but this is present in the shape of a smaller or larger compact chromatin body, which stains intensely, and by most staining methods is surrounded by a narrow unstained zone. By the special staining method which Feinberg used he was enabled to stain this zone, and thus demonstrate that it is in no sense a vacuole. The bodies which Feinberg has described as microorganisms in carcinomatous tissue correspond entirely to the above histological requirements of single-cell organisms, and must be considered as such unless the established facts of histology are to be thrown aside. The demonstration of their presence is, of course, only the first step in the solution of the etiology of carcinoma, but their presence in such tissue is not to be doubted. The author has simply shown their presence in large numbers in fresh carcinomatous tissue, and pointed out that they very probably hold an etiological relation to this disease.

Berliner klinische Wochenschrift, January 26, 1903.

Etiology of Osteoarthropathic Lesions.—Walter Berent reports a case which shows the intimate relations which exist between nerve lesions and osteoarthropathic changes. So far as the latter were concerned, the case corresponded closely to one of "osteoarthropathie hypertrophiante pneumique," as described by Pierre Marie. The left upper extremity alone was involved. Examination revealed the presence of an aneurysm of the left subclavian artery, which was of long standing and exerted marked pressure upon the brachial plexus, causing thickening and pain in the larger nerves which supply the left upper extremity, together with secondary degenerations in the peripheral branches of the same. Other authors have regarded osteoarthropathic lesions as dependent upon nerve changes. The present case beautifully illustrates the connection between these and adds increased weight to the opinion that the bone changes are primarily due to nerve degenerations.

French and Italian Journals.

Condition of the Pelvis in Women Who Have Undergone Several Symphyseotomies.—Poirier speaks of a rachitic patient who has had nine children and has submitted to three symphyseotomies. As a result of these operations, there is a disjunction of the pubic bones which are separated by an interval of from 2 to 2½ cm. Into this breach the little finger can be inserted. A fibrous band connects the two parts in the form of a membranous bridge. But the great disadvantage to the patient is that on account of the mobility of the two parts of the pelvis, there is marked limping and discomfort in walking.—*La Presse Médicale*, January 24, 1903.

Sarcoma of the Superior Maxilla.—Derocque operated on a woman, forty-two years of age, suffering from sarcoma of the superior maxilla. She insisted that the operation leave as slight a trace as possible. After incision, as for total resection of the maxilla, section of the anterior wall of the sinus was performed with the scissors. After the ablation of this, it could be seen that the tumor, which was encapsulated, filled up almost the whole of the sinus. The alveolar border was almost entirely involved. Ablation of the maxilla was accomplished, the floor of the orbit being left. There was no deformity of the face. In tumors well limited, it is most useful to preserve the orbital floor, as this prevents the slipping of the ocular globe and holds out the cheek sufficiently to avoid deformity.—*La Revue Médicale, de Normandie*, January 25, 1903.

The General Pathology of Peripheral Neuritis.—S. Bianchini concludes from his experimental researches that many of the sensory lesions which accompany neuritis, whether they be irritative or degenerative, are referable to a primary local alteration of some portion of the peripheral fibers, more especially perhaps in the neurilemma. Moreover, these peripheral lesions react upon the medullary centers and the ganglia, and constitute a predisposition to toxic influences. The application of these conclusions may throw light on certain forms of neuritis in which there is apparently an ascending process, especially in some cases of Landry's paralysis in which the profound and irreparable lesions of the medullary and bulbar centers follow an initial peripher lesion.—*Rivista Critica di Clinica Medica*, January 17, 1903.

A Case of Multiple Cicatricial Cheloids.—Luigi Trabucchi reports the case of a young man who was affected with cheloids which extended from the upper margin of the third rib down to the left hypochondrium, and from the hemiscapular line posteriorly to the parasternal anteriorly. The growths varied in size from a pin head to a pigeon's egg, the largest being near the middle axillary line. The patient gave a history of pleuritis two years previously; treatment consisted of the application of tincture of iodine, followed by an unguent composed of antimony and potassium tartrate and croton oil. The use of this ointment was followed by a pustular eruption, which healed somewhat rapidly under treatment with some application of whose composition the patient was ignorant, but the more severe lesions left cicatrices which hypertrophied and assumed the dimensions above stated. There were about eighty of these cheloid growths.—*Gazzetta Medica Lombarda*, January 25, 1903.

Neurasthenia and Its Treatment.—C. N. de Blois gives as some of the causes of this affection: Late hours, excessive manual labor, mental work, emotion, grief, and severe traumatism, as railroad accidents. There is also a nervous heredity which creates false neurasthenia. The stigmata are of two kinds: Objective and subjective. Sometimes the patients look perfectly well. The subjective symptoms are generally on the psychical order. Insomnia is one of the most important and frequent symptoms. Of the gastrointestinal phenomena, the most predominant is difficulty and slowness of digestion. The mental condition varies greatly. There is no special diet for the neurasthenic. The ordinary mixed diet suitable in the majority of cases of gastrointestinal atony, is indicated. In the larger number of cases, short journeys, especially during convalescence, are indicated. They are one of the best means of obtaining distraction without effort. A friend should always accompany the patient.—*Le Bulletin Médical de Québec*, January, 1903.

Fibroma of the Thyroid Gland.—Vassile Ourmanoff, in his recent thesis, discusses this interesting subject. The fibroma of the thyroid is an interesting tumor on account of its extreme rarity and on account of the difficulty in its diagnosis. The writer has gathered together five authentic cases. The symptomatology is analogous to that of carcinoma, and the course, to that of a sarcoma of rapid growth. Minute study is necessary to differentiate it; often, indeed, the anatomo-pathological examination alone, after operation, permits the establishment of the nature of this affection. The etiology is as unknown as that of other thyroid tumors. The pathological anatomy has been carefully studied; macroscopically, it can best be compared with a typical uterine fibroma; microscopically, it is constituted a pure fibrous tissue. An important characteristic is the encapsulation of the neoplasm. The only treatment consists of total extirpation, it may be *en mass*, it may be piece-meal. The operative prognosis seems good. The five cases operated on have been successful.—*Lyon Médical*, January 25, 1903.

The Mimicry of Gastric Troubles by Spinal Disease.—Sir Frederick Treves says that a very short experience in the out-patient department of a large hospital will reveal the person of a child who is reputed to be suffering from some gastric trouble, but who is, in reality, the subject of caries of the spine. Such a child will complain of little more than an abiding pain in the stomach. The pain will probably be about the umbilical region, in the area supplied by the eighth, ninth, and tenth dorsal nerves. The pain is due to the fact that there is an unsuspected caries of the dorsal spine, and the nerve or nerves in question are pressed upon or are in some other way disturbed. The pain survives the administration of rhubarb or castor oil or other aperient; it is upon the surface, encircles the body, and abates when the patient lies down. The tongue is clean and there is no nausea or vomiting. These examples of mimicry when they occur in adults are apt to be even more deceptive. The moral to be derived is, that suspicion should be aroused as to the genuineness of gastric trouble when pain is the all-predominating symptom, when it is intense and persisting, and when vomiting is at the same time either absent or insignificant.—*The Practitioner.*

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held February 5, 1903.

ANDREW H. SMITH, M.D., PRESIDENT.

Symposium on Tuberculosis.—This was the special subject for the evening, and the meeting was in charge of the Section on Medicine.

The Practical Recognition of the Tubercle Bacillus in Sputum.—Dr. CHARLES B. FITZPATRICK of the Bacteriological Division of the New York City Board of Health read this paper. He said that, according to the usual method of procedure, the tubercle bacilli were stained red and the balance of the field blue. His own method was as follows: A moderately thin layer of sputum should be spread upon a cover glass, selecting the cheesy portion of the sputum. The smear is allowed to dry in the air, or in an oven having a temperature of 50 to 60° C. After drying, it is passed three times through the flame. The preparation is next placed in a fresh solution of Ehrlich's anilin fuchsin. If the smear has been made upon a cover glass, a watch crystal full of anilin fuchsin solution is employed, and the preparation floated upon it with the smeared face downward. The watch glass is then seized with forceps and held over a small flame until the fluid in the watch glass begins to bubble. It is then removed from the flame and allowed to stand for one minute. The smear is next removed and washed, after which it is placed in a decolorizing solution. This is composed of three parts of hydrochloric acid and ninety-seven parts of 70-per-cent. alcohol. The smear should be gently moved from side to side in the solution until it becomes almost colorless. This usually requires about one minute. The next step is to wash off the decolorizing solution with running water, to remove the acid. The smear is then covered with Loeffler's alkalin solution of methylene blue. This contrast stain is allowed to remain on the smear one or two minutes, or until the preparation becomes of a distinct blue. This is then washed off, and the smear is allowed to dry in the air, or is dried with filter paper. It is next passed rapidly through the flame several times. The cover glass is finally mounted in xylol balsam. If the preparation be examined with a one-twelfth oil immersion homogeneous lens and a No. 3 ocular, the tubercle bacillus will appear as a minute red or pink rod, and the other parts of the preparation will be stained blue. Sometimes there are minute bodies like beads observed, which are composed largely of fat. When this beaded appearance of the bacillus is observed, the following modification of the method should be adopted: The smear should be thoroughly dried at room temperature and without passing it through the flame. It is placed in the Ehrlich anilin fuchsin solution for from four to twenty-four or forty-eight hours. It is then washed, decolorized, and stained with the contrast stain as already described. Instead of being passed through the flame as a final step, it is dried with filter paper and is then allowed to dry in the air of the room. Ehrlich's anilin fuchsin solution is made by mixing 4 c.c. of anilin oil with 100 c.c. of water and shaking thoroughly. Filter the solution through a wet filter and add 11 c.c. of a concentrated alcoholic solution of fuchsin and shake thoroughly. This solution should be made fresh every third day in order to secure the best results.

The speaker said that strong decolorizing agents gave unreliable results. A 20 per cent. nitric acid decolorizing solution, for example, would often decolorize the tubercle bacillus, and then the contrast stain would color the bacillus blue. He had succeeded in decolorizing some tubercle bacilli with this strong decolorizing solution in one or two minutes. The Loeffler alkaline solution of methylene blue was composed of 30 c.c. of a concentrated alcoholic solution of methylene blue and 100 c.c. of a 1-to-1,000 solution of caustic potash. There were different varieties of the tubercle bacillus, but the typical organisms, according to his experience, could always be stained by the method just outlined, so that it could be identified. This method had been used in the examination of about 30,000 specimens of sputa.

The Sanatorium Treatment of Tuberculosis.—Dr. HERBERT M. KING of the Loomis Sanatorium, Liberty, N. Y., was the author of this paper, but on account of its length he only read portions of it. He said that the sanatorium for tuberculosis should be located at an elevation of about 2,000 feet whenever possible, and in a region having pure and stimulating air. In the matter of exercise and feeding there were no hard and fast rules applicable to all cases. Each individual was a law unto himself and should demand treatment irrespective of the class to which he belonged. The laboratory should be equipped not only for the ordinary clinical work, but for research as well. He suggested further study into the problems of metabolism, and into the effects of sera and the various states of the blood found in tuberculosis. From the statistics of Trudeau, it might be said that the minimum term of residence for a simple and uncomplicated case should not be less than three months, whereas for the moderately advanced incipient cases the minimum should be six months. After "an economic cure" it was often practicable to allow the patient to return to his home, if the latter were amid healthful surroundings. It had been his experience, and that of other sanatorium physicians, that the patients did not find the discipline of such institutions irksome. At the Loomis Sanatorium the newly-admitted patient was sent to the infirmary for examination and observation, and was usually placed in bed. The history was taken in accordance with a printed chart, so as to secure uniformity and thoroughness of record. Dr. Trudeau divided his cases into incipient, moderately advanced, and far advanced; the speaker preferred to subdivide each of these groups, so that early cases were grouped into those showing mild and those showing acute symptoms; the advanced cases were divided into those with favorable and those with unfavorable symptoms, and the long-standing cases into those in which fibrosis predominated and those in which ulceration was the prominent feature. The newly-admitted patients were compelled to rest for the first few weeks, using a reclining chair on the veranda for from six to ten hours a day, the amount of outdoor exposure being regulated in accordance with the weather. During the night the patient slept in a room with the windows wide open, and in the early morning a nurse closed the windows and warmed the room before the patient got out of bed.

Exercise.—With regard to exercise after this period of enforced rest, it should be said that an average pulse rate of 100 or more while the patient was at rest contraindicated exercise, as did also a rectal temperature in the morning of 99° F., or an afternoon rise to above 100° F. The failure to increase in weight was also looked upon as a contraindication. The first exercise should be in the nature of an experiment, and should not be more than a quiet walk for a few hundred yards. After this some slight and simple chest exercises might be employed, and then, still later, hill climbing could be cautiously tried. It should be the rule to insist upon rest before and after meals for those patients who exercise.

With the ordinary patient, unless the weight were far below normal, three hearty meals a day should be given if the patient were out in the open air. Forcing the diet beyond the point of comfort was, according to his experience, an unwarranted practice, and was sure to be followed by indigestion. There was this advantage in forced feeding, that the stomach which had rebelled against any food became accustomed to a fair quantity of food, and the patient was soon able to take a fair quantity of food in the usual way. It had been proved very conclusively that

tubbing for the reduction of temperature in septic cases of tuberculosis was not only of little avail, but was actually harmful. On the other hand, tepid sponging, or the employment of the wet pack in such cases was to be recommended, and had proved very valuable in controlling the fever. The refinements of hydrotherapeutics were useful when elimination was deficient and appetite and digestion imperfect. In the summer no difficulty was experienced in selecting suitable recreation. Golf was healthful amusement, but only short plays should be allowed, except for those whose condition was exceptionally good.

The Treatment and Care of Consumptives at Their Homes and the Urgent Need of Local Sanatoria.—Dr. S. A. Knopf read this paper. (See page 281.)

Dr. E. G. Janeway opened the general discussion. He said that undoubtedly the State of New York had been most reprehensible in its attitude toward the State Sanatorium for Consumptives, for, after three years, only the cellar had been built. The city of New York wanted not only a local sanatorium for its consumptive poor, but a place in which to educate the masses on this subject. It was largely because of the enormous number of consumptives that needed sanatorium treatment that the municipality and the State were so reluctant about venturing upon this great task. At present there was a proposed reform of the tenement-house law, a reform which would help the pockets of the builders and the tenement-house owners, and those who loaned money for these enterprises. The Academy of Medicine should urgently protest against any change in the tenement-house law.

Dr. S. A. Knopf then introduced the following resolution, which was laid over under the rule:

Whereas, Strenuous efforts are being made to induce the Legislature to utterly undo the great advances made in recent years in tenement-house reform and sanitation, and to prevent the permanent carrying into effect of the great improvements in the construction and management of tenement-houses in New York and Buffalo, which have been made possible by the recent Tenement-house Law; and

Whereas, Pulmonary tuberculosis is extremely prevalent in the City of New York, there being eight thousand deaths and twenty thousand cases annually; and

Whereas, The lack of air and light in the rooms of the great masses of the people is one of the most potent causes in increasing the prevalence of this and other communicable diseases, and constitute serious menaces to health and morality, be it

Resolved, That the New York Academy of Medicine deplores any weakening of the present tenement-house laws, and urgently requests the Legislature to permit no changes to be made that will in any way decrease the amount of light and air available for the people living in such houses, or in any way take a backward step in regard to their sanitary condition.

Dr. S. S. Burt spoke briefly in favor of the movement to increase the number of sanatoria for tuberculosis.

Dr. Beverly Robinson heartily endorsed all that Dr. Knopf had said, but felt that some of the money which it was proposed to spend for private sanatoria could be more wisely used to send competent and sympathetic teachers among the poor to show them how they could best take care of themselves and battle with disease. Some of the good ladies of the city were spending much time and energy in promoting the work of a sanatorium in the woods for consumptives, and yet these same estimable women not infrequently were guilty of sweeping our dirty streets with their long dresses and scattering disease germs broadcast.

Value of the Clinical Thermometer in Tuberculosis.—Dr. Henry P. Loomis spoke of the very great importance of using the clinical thermometer as a guide to both the diagnosis and management of pulmonary tuberculosis. It had been his habit for the last few years to provide the patient with a thermometer and have the temperature taken regularly, so that he could be kept informed regarding the temperature range between his visits. This plan was of great service, and the only valid objection to it was that it might make the patient unduly apprehensive. Such a record would often give the attending physician an entirely different notion of the type of disease he was treating. Many persons had expressed doubt as to whether persons in an early stage of the disease could be persuaded to give up their occupation and seek treatment in a sanatorium, but the education of the people had been going on constantly, and he believed that even now many persons with the disease in its incipiency would be willing to seek such care. The trouble was that these sanatoria should be absolutely free, for, many of those most needing such care were unable to pay even five dollars a week. The practical difficulty came in here, for those who had not made a special study of the subject had no conception of the great expense involved in conducting such sanatoria.

Fire Escapes for the Treatment of Consumptives in the City.—Dr. Alfred Meyer said that such discussions as these impressed him deeply with the fact that the medical profession was working cheerfully and earnestly against its own financial interests, and that their efforts were directed toward far higher ideals than mere money-getting. The Academy of Medicine had not been backward in this work, and the municipality had been urged to do what private philanthropy had been unable to cope with. We all knew that, so far as New York was concerned, there was a continual reduction in the mortality from this disease, and, from inference, we could say in the morbidity as well. He understood that there had been a decrease of 10 per cent. in the past year over the preceding year despite the increase in the population of the city. The speaker went on to say that he would plead guilty to the indictment of having used the fire escapes for the treatment of pulmonary invalids. He knew there was an ordinance prohibiting the obstruction of fire escapes, but he felt justified in this infraction of the law, and even in urging his colleagues to adopt the same plan, and he felt sure public opinion would not tolerate any interference with this life-saving procedure.

Health Department Statistics.—Dr. Herman M. Biggs said that the crusade of the Health Department against tuberculosis had been going on since 1887, and he was glad to see that the attitude of the Academy of Medicine, and of the local profession generally, had changed with reference to this subject. During the last five years a semi-annual census had been made of the tuberculous patients under treatment in all of the city institutions, and this census had shown almost uniformly that there were from 800 to 1,000 such patients under institution care. Of the total number of deaths occurring in the city each year, about 40 per cent. were in institutions; hence in the 1,000 beds available for consumptives in New York City, about 2,000 deaths occurred each year, or about two deaths for each bed. These beds were really for hopeless, helpless, and, usually, homeless consumptives. Of the 2,000 dying in institutions each year, nearly one-half were without friends, home, or money. During the past year there had been reported to the health department in the Borough of Manhattan about 9,000 cases of tuberculosis. The deaths during this same period had been about half of this number. All of these reported cases, except those under the care of private physicians, were visited by the inspectors of the Health Department. Two difficulties were met with in the removal of these patients from their surroundings. Very few of these persons were willing to enter any of the few available institutions as long as they were able to obtain a livelihood in any way outside. Much had been said about needing *more* sanatoria, but, as a matter of fact, we had *no* sanatoria except it might be the one at Bedford Station. On an average, the inspectors visited 100 such

patients a week, and almost all of these unfortunate persons had no proper place to go to. A recent letter from the Chief of Staff of St. Joseph's Hospital informed him that there had been about 300 deaths in that institution during the past year and that this number would probably be much larger next year because seventy-five more beds had been set aside for dying consumptives. He did not think there would be any great difficulty in inducing tuberculous patients to go into sanatoria provided a reasonable hope of benefit could be held out to them. The Seton Hospital was now largely devoted to the care of consumptives under a special appropriation from the city, and the same persons who would flatly refuse to go to the ordinary city hospitals were glad to avail themselves of the privileges of the Seton Hospital. About 80 per cent. of the cases of tuberculosis were now reported to the Health Department before death, and from this it was estimated that at least 16,000 cases were present in the Borough of Manhattan in a stage in which the disease could be recognized, and that at least two-thirds of these were in the tenement-houses.

Tuberculosis Decreasing.—The statement had been frequently made that tuberculosis was increasing, but this was far from the truth. It was, on the contrary, rapidly decreasing in this city. Since 1886 there had been a decrease in the death rate from all tuberculous diseases in the boroughs of Manhattan and the Bronx, the old city, of 40 per cent., the death rate in 1886 having been 4.5 per thousand of the population, whereas in the past year the death rate was 2.68. There was but little question that with greatly increased hospital facilities for advanced cases, and with large sanatorial facilities for incipient cases, and with an extension of the educational work now being done, the death rate from tuberculosis would decrease as rapidly in the future as it had done in the past, and that in another fifteen years the death rate would not be over 1.5 or 1.7 per thousand of the population.

Tuberculin.—Dr. C. B. Fitzpatrick said that nothing had been said about tuberculin, yet he thought the use of this agent in early and doubtful cases promised to yield good results.

Dr. H. M. King said that post-mortem study showed that the healed tuberculous lesions found in the autopsy room were invariably those of the very early stages; in other words, before softening had occurred. If such early cases came under sanatorium treatment, he felt sure that 60 per cent. would be cured.

Dr. Knopf said that he fully appreciated the importance of keeping a record of the temperature, but as tuberculous patients were, as a class, very nervous, he found that if they were allowed to take their own temperature they were apt to become so wrought up about it as to cause an increased elevation of temperature. It was much better, therefore, to have the physician or nurse, or in lieu of these, some other member of the patient's family, take the temperature, and the result of the reading of the thermometer should be kept from the patient.

Prehistoric Pygmies.—A German anthropologist, Herr Thilenius, has recently shown that pygmies—now only found in the interior of Africa—were, during prehistoric times, spread over parts of Europe. Numerous skeletons found in Silesia show that the stature of the men they represent was not much above 4½ feet. There were pygmies in Switzerland and in Alsace also. These dwarf races were in no wise degenerates. They appear to have persisted up to comparatively recent times. The pygmies of Silesia, for instance, were contemporary with the Romans and they continued up to the tenth century. At present there is no vestige of such a race, but their skeletons remain to prove their existence.—*New York Sun.*

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held January 26, 1903.

Charles N. Dowd, M.D., President.

Trachoma; Clinical History and Treatment.—Dr. Frank Van Fleet presented this paper. He said that trachoma was a contagious disease affecting primarily, not the eye itself, but the conjunctiva. Its onset was often insidious, and he believed in some instances it passed through its various stages without seriously inconveniencing the victim. The disease was of mild type in this country as compared with that observed in Egypt and in some other lands in which the poor people were badly housed and were more ignorant of what constituted sanitary living. The positive differentiation of trachoma and follicular conjunctivitis must continue to be more or less a matter of opinion. The first symptom of trachoma was a feeling of irritation of the eyelids, most noticeable after much use of the eyes. Sometimes the use of glasses, by correcting the refractive errors, might, for a time, relieve trachoma. The irritation referred to was manifested by an itching and burning of the eyes and a blurring of fine print when reading. On awakening in the morning the white of the eye was reddish, and there was a little hardened secretion in the corner of the eye. The speaker said that he had seen a great many cases of chronic trachoma, occurring in children, excluded from school by the health inspectors, though the symptoms were no more marked than this. As the disease progressed the eyelids became altered in contour because of the increase in size of trachoma follicles. The ocular conjunctiva became thickened and œdematous, and the small rounded elevation at the inner angle, the caruncle, became larger, and of an angry appearance. The peculiar succulent look of the lid at this time was very characteristic of trachoma. At this stage the eyelids were apt to be glued together on awakening in the morning. On everting the eyelids one would see a thickened, reddened surface, studded with more or less numerous enlarged follicles, with enlarged blood vessels running across it. As a rule, the eye itself was not involved in this stage, and in the American-born children of our schools the disease did not usually progress farther. In the chronic form the eye itself was affected by reason of the increase in size of the follicles, and the coincident induration. On everting the lids, the palpebral conjunctiva presented an appearance not very different from that observed following other inflammatory diseases of the conjunctiva. The latter presented a thick, velvety surface, looking more like the conjunctiva denuded of its natural covering than like the mucous membrane. Sometimes the palpebral conjunctiva presented a granulating sore. Later on, the thickened tissues seemed to undergo contraction, and the eye itself became involved by the thickened and roughened conjunctiva rubbing over the cornea. Ulceration and perforation of the cornea seldom occurred in trachoma. In the cicatricial stage the lids could not be opened widely, and there was a tendency of the tarsal cartilage to curve inward. As a result, first the edges of the lid and then the lashes turned in. It was impossible to make a differential diagnosis of trachoma in all cases. Many cases of blepharitis presented the reddened lids and the succulent appearance, but there would be no follicular involvement. He could see no reason for differentiating trachoma at all, and it was safe to say that the presence of an inflammation of the eyelids associated with the discharge of pus denoted the presence of a contagious disease of the eye. Any attempt to separate the various forms in accordance with the degree of intensity must be fanciful and unproductive of any good result.

Pathology.—Dr. Arnold H. Knapp presented this paper. He said that the enlarged follicles of trachoma were known anatomically as lymph follicles. There was no

difference anatomically between the lymph follicles of follicular conjunctivitis and of trachoma. These follicles were most numerous in the retrotarsal folds, and infiltrated in the direction of the caruncle and of the palpebral conjunctiva. The disappearance of the follicles might leave no visible scars, or only a whitish tendinous transformation of the conjunctiva. Associated with the trachomatous process were hypertrophy and degeneration of the epithelium, but without true ulceration and destruction. Histologically, there was a diffused round cell infiltration and an œdematous swelling; later, new blood vessels were formed. The inflammation of the tarsal portion was secondary. The corneal changes had not been definitely explained. Assuming that trachoma was a process of follicle formation, it was found that it differed from other follicular diseases in the size of the follicles, and in the clinical course. Follicles were met in chronic syphilis and tuberculosis of the conjunctiva, and after the prolonged use of atropine and other eye drops; hence it was evident that the follicle of trachoma was merely a symptom. It was probable that trachoma was due to a microorganism. Acute trachoma was due to a mixed infection, the acute character being the result of a fresh infection with the gonococcus, the Weeks bacillus, or the pneumococcus.

Treatment.—Dr. J. HERBERT CLAIBORNE presented this part of the subject. He divided trachoma into non-inflammatory and inflammatory. The former, he said, was characterized by the existence of sago-like grains on the mucous membrane of the upper and lower lids. Particular stress was laid upon the fact that the granulation must be on both upper and lower lids. The form of trachoma known as follicular was restricted to the lower lid, and was particularly seen toward the outer canthus. The picture presented was so marked that it could hardly fail of recognition. He looked upon this form as contagious. The other form of trachoma was sometimes known as Egyptian or military ophthalmia, though he saw no reason for applying either term. Its onset was characterized by acute inflammation, lachrymation, photophobia, and a great amount of discharge. Subsequently, granulations formed on the upper and lower lids, constituting the secondary form of the disease. The granulations finally coalesced, and pannus and opacity of the cornea occurred. While the cause of trachoma was not known, it was a significant fact that mechanical treatment was the most efficient for a disease which was suspected to be of microbic origin. Many would recall the treatment of trachoma by jequirity, a remedy which produced a violent form of inflammation. It should never be employed except in a few cases presenting pannus—indeed, it was perhaps safer not to use it at all, for the records showed that a number of eyes had been lost under this treatment. Silver nitrate had always been a favorite agent with those who had not met with the severer forms of trachoma. It was of slight value in the treatment of real trachoma. The use of zinc as a palliative and supplement to severer measures was to be recommended. Solutions of bichloride of mercury in various strengths had been used by some. Formalin, in the strength of 1 to 5,000 and 1 to 10,000, had been used lately with benefit by some surgeons. However, the sulphate of copper sticks, ground smooth and in the shape of a parallelogram, so thin that they could be readily introduced under the lid, were preferable. The upper lid having been everted, the stick should be applied delicately and gently underneath the upper lid in the cul-de-sac. Subsequently the cul-de-sac of the lower lid should be gently stroked with the stick. The tears caused a solution of the copper, and this excess should be wiped away. The pain in some cases was considerable, though in the majority of instances it was not so severe as generally supposed, and much depended upon the delicacy of manipulation of the person making the application. He considered it impossible to disinfect camel's-hair brushes, and hence did not advise their use. Of course the sanitary surroundings of the patient should be regarded.

Surgical Treatment.—The surgical treatment depended upon the kind, extent, and stage of the disease, and its intensity. The form presenting the sago-like grains yielded the most brilliant results. Perhaps the oldest mechanical treatment was the brushing or scratching of the granules, a method which had been employed with some success by a number of surgeons in this city at the New York Eye and Ear Infirmary. It had been used both with and without scarification. The after-treatment consisted in the application of astringents and antiseptic washes. This method, however, had been practically eliminated from surgery, and now had chiefly a historical interest. He had used the actual cautery with the platinum probe in a number of cases. Another method of treatment was by curettage under cocaine anæsthesia, but the treatment was needlessly long. The use of scissors for cutting away the follicles was at one time in vogue, but the method fell into disuse because of the destruction of the submucous tissue. The most effective form of treatment was that known as expression. It had first been recommended as long ago as 1873. In 1891 Dr. Prince had invented a ring-shaped forceps, which was one of the best instruments for this purpose, with the exception of the roller forceps more recently devised by Dr. Knapp. The granules were rolled between the cylinders and their contents expressed. This instrument was distinctly one for force, but not for laceration. The rollers were applied to the mucous surface of the lid folded upon itself. When all of the granules had been expressed on the upper lid, the lower lid was treated in such a way as to destroy the granules there. General anæsthesia was needed for this operation, and ether appeared to be the best agent, though, perhaps, a better plan was to give ethyl chloride for two or three minutes and then push the ether. After the operation many surgeons rubbed into the conjunctiva strong bichloride solutions, while others used the solid stick of sulphate of copper. Dr. Claiborne preferred to direct that the eyes be kept clean for a day or two, and then use zinc or boric acid solution until the post-operative membrane had disappeared, and then use for a few days a one-per-cent. solution of nitrate of silver, and after this the stick of sulphate of copper. He saw no reason whatever for keeping these patients in the hospital ward over night. In the treatment of the severe form of trachoma it was his rule to resort to expression so long as granules could be seen; after that, medicinal treatment, the use of copper sulphate, was indicated. It was the custom of some ophthalmologists to use atropine whenever there was pannus on the supposition that iritis was always present, but he was convinced that iritis was not always so associated, and as under other conditions atropine, being an irritant, was contraindicated, he rarely made use of it in these cases.

Present Conditions in This City.—Dr. WALTER EYRE LAMBERT presented the subject from the point of view of public health (see page 293).

Prophylaxis.—Dr. A. E. DAVIS said that under the ruling of the United States Treasury Department in 1897 it became possible to exclude all immigrants affected with trachoma. The first year one case of trachoma to every thousand immigrants was reported; in the second year this proportion was one to 1,500, and in the third year, one to every 2,100 immigrants. This showed a marked decrease in the number of immigrants of this class. It was not, however, until 1901 that the inspection at our ports was at all thorough. It was then found that the steamship companies were booking all these immigrants via Canada, and that coming in by that route was one case of trachoma for every 130 immigrants. Canada was now co-operating with us, so that this had

been stopped. The speaker said that in 1891 he had gathered the statistics of about half a million cases of ocular disease, and had found that of this number trachoma represented 4.525 per cent. From the same sources he found in 1901 that this percentage had been reduced to 2.75. It had been shown that in the asylums for the blind in this city 4.2 per cent. of the cases were due to trachoma, and that in Chicago the percentage was 9.9. This showed the great importance of this subject to the community.

Dr. Thomas R. Pooley thought there was a great deal of confusion concerning the form of the disease present in this city. The form of trachoma existing in this city to-day was, in his opinion, the non-inflammatory one. He had described this in a paper read before the Section on Ophthalmology of the New York Academy of Medicine in 1900. The differentiation appeared to be unimportant; the great point to remember was that trachoma presented itself in the form which, if left to itself, would probably do much damage to these eyes. So far as he knew, no specific microorganism had been discovered for this disease; hence the microscopic findings were the same whether the disease was called follicular conjunctivitis, follicular trachoma, or simple trachoma. It would be instructive to treat a series of cases by expression, and another series of cases by mild remedies, and note the results. This seemed to be the only way of settling the question of the best mode of treatment. Whether the disease was considered as follicular disease or as true trachoma it had become very common in institutions in which many children were congregated together. This statement was equally true of follicular conjunctivitis and true trachoma, so that here again the disease must be considered contagious. He could not accept Dr. Van Fleet's statement, that the proper use of eyeglasses might avert the appearance of trachoma, and he deplored the fact that such a statement had been made. In his experience, it was the rarest thing to see a case of acute trachoma; most of the cases met with came on with very few inflammatory or subjective symptoms. The use of jequirity had not entirely gone out of vogue; a number of ophthalmologists had lately returned to it, although they were employing it with much greater caution than before. It was certainly a very dangerous plan of treatment, yet if proper precautions were observed there might be some justification for returning to this treatment. He had yet to see an undoubted case of infection resulting from the use of camel's-hair brushes in the dispensaries, and he believed if these brushes were thoroughly washed this would be enough, although, of course, it was better to make use of antiseptic solutions. To his mind, grattage was one of the most objectionable and abominable and reprehensible modes of treatment ever devised. It produced a number of parallel scarifications of the conjunctiva, and added to this injury the rubbing in of a strong solution of bichloride of mercury. The inevitable result of such treatment was to destroy the conjunctival membrane and substitute therefor connective tissue. It had very justly been abandoned. The expression method of treatment was one of the most useful and important innovations in modern ophthalmology. It was perfectly applicable to the class of cases now generally met with. He believed it would effect a cure in all of these cases if the operative measures were followed up by appropriate treatment. In a previous paper he had discussed the tendency to recurrence of this disease. A carefully-selected series of cases showed a cure in 96 per cent. In these cases the conjunctiva was smooth, and there was a disappearance of all hypertrophy and granulation of the conjunctiva. He was not disposed to lay very much stress upon the special instrument employed for this operation; it was not so much the instrument as the deftness of the operator. The roller forceps was the best instrument yet devised for the purpose, and in careful hands could be used to secure a perfectly smooth condition of the conjunctiva without tearing the latter. These were the two essentials of this treatment. The chief points of the after-treatment were to keep the conjunctiva clean and aseptic, and apply astringents as soon as the operative reaction had disappeared, continuing this treatment for a considerable time. It was utterly unnecessary to keep these patients in a hospital. If the operation had been carefully performed, and the eye was kept thoroughly cleansed thereafter, there was little or no danger of contagion, and hence there was no objection to such patients going home.

Dr. J. E. Weeks said that in 1890 the mechanical treatment of trachoma was but little thought of in this city, and those who had expressed themselves this evening as enthusiastically in favor of it had been very doubtful ten years ago regarding its efficacy. If the treatment were instituted in the first stage of trachoma, or that in which the follicles were discrete, a cure could be effected in from two to four weeks, whereas in the later stages the time of treatment might vary from three months to almost as many years. The post-operative treatment was very important. Allusion had been made to the "post-operative membrane." This "membrane" was a layer of fibrin which united the folds of the conjunctiva, and these must be broken up in order to avoid a permanent union of these two layers. This could only be done by careful after-treatment. If this were done there was nothing else required but the cleansing of the conjunctiva. The bluestone treatment was painful and, in his judgment, was not necessary. He had operated upon many patients during the past eight years, and not one of them had returned with a recurrence. Recurrence should be rare if care were taken to remove all the granules from the conjunctiva.

Dr. D. H. Wiesner said that last June, in company with several other medical gentlemen, he had examined two of the schools of this city. In one of them they found 4.5 per cent. of severe trachoma and 7 per cent. of mild trachoma; in the other, 8 per cent. of the severe form and 5 per cent. of the mild form. One of these schools was far down on the East Side; the other on the same side of the city, but not so far down town. The public baths in the summer constituted a not unimportant source of eye infection. At that season of the year many cases of acute catarrhal conjunctivitis could be traced to these baths, and he was inclined to think that many cases of trachoma arose in this way also. He thought it would be well to have those baths subjected to medical inspection. In the treatment of trachoma he had found the application of the stick of sulphate of copper very painful. On the contrary, he had found tannic acid very useful when applied in the strength of two drachms to one ounce of glycerin. It should be applied to the lids, everting the upper lid. The smarting produced by this application passed off very much more quickly than that caused by the use of the stick of sulphate of copper.

Dr. Wilbur B. Marple said that lately Merck had introduced the active principle of jequirity. Many years ago he had made use of jequirity, but like many other had abandoned it until a short time ago. In the new form of the active principle, jequiritol, it seemed possible to use it with greater safety. He had found that a sublimate solution, 1 to 500, was usually just as efficient as the sulphate of copper, and very much less painful.

Dr. Pooley said with regard to the adhesion of the lids as a result of the fibrinous exudate, that he had never seen such a result, and hence could not appreciate the necessity for the treatment insisted upon by Dr. Weeks. He was also surprised at the statement from the same speaker, that sulphate of copper was of no value. He would meet this with the equally dogmatic statement that this agent was of very great value.

The Disease Mild among Our School Children.—Dr. Charles B. Meding said that in the past four months those who had given personal attention to all applying at

an infirmary must have noticed that while there had been a constant influx from the public schools there had also been the regular run of trachomatous cases. The great difference between the two classes was that the cases belonging to the first class were promptly cured, while the others proved most obstinate. He mentioned this to emphasize the fact that these cases from the schools must be of a different nature from the type of trachoma with which all ophthalmologists were familiar year after year. Perhaps this difference in the class of cases also explained the varying opinions expressed with regard to sulphate of copper, tannin, and other agents. The tractability of the cases found among the school children suggested the advisability of allowing these children to return to the schools under suitable supervision. The importance of this subject might be better appreciated when he said that, in a small infirmary uptown a number of children had lost 1,500 days of schooling, and yet none of them could be said to be a serious menace to the public health.

Dr. Herman Jarecky said that as a rule these children were readmitted to school on the receipt of a letter from a specialist stating that the children had been operated upon or properly treated; hence, there should not be much schooling lost. He had seen tannic acid used quite extensively in these cases with a good deal of benefit, and what was equally important, with less tendency to the formation of scar tissue than when sulphate of copper was used.

Dr. W. E. Lambert thought it was very necessary that trachoma patients who were operated upon should be retained in a hospital at least for the first night. This not only assured proper recovery from the anæsthetic, but made it possible to carry out the after-treatment thoroughly. He thoroughly agreed with the speaker who had pointed out the fact that the public baths were a source of eye infection. He had recently brought this subject again to the notice of the Health Commissioner, and had learned that these baths had been placed under medical inspection. In two or three baths so inspected the proportion of contagious disease was found to be 25 or 30 per cent. He could not understand how anyone familiar with the present condition of the eyes of our school children could speak with regard to the comparatively small matter of the loss of a little schooling. It was true that the inspectors had made some mistakes, but all of these had been on the side of safety. He would again insist upon the importance of these inspectors being skilful and fully competent thoroughly to expose and examine the upper cul-de-sac.

Dr. Meding said that he was fully aware that many of the school children had trachoma, but he was speaking of many specific cases, found not to be contagious, and of many cases so mild that he thought attention should be called to it, and due consideration be given it.

Overcrowding of Street Cars.—Dr. Charles G. Kerley said that, as chairman of the committee appointed to consider this subject, he had attended one meeting of the Merchants' Association, and it had been suggested there that the Medical Society of the County of New York could aid in this work by sending to the New York State Board of Railroad Commissioners a communication dealing specially with the subject from the point of view of public health. Dr. Kerley then presented, as the report of his committee, a communication of the kind that had been suggested. This communication pointed out the opportunity afforded for the transmission of disease by this overcrowding of the cars, the impossibility of securing proper ventilation, and the consequent danger of contracting bronchitis and pneumonia from the opening of the doors. It also called attention to the need for greater cleanliness in the cars and on the stations, and the importance of doing away with matting and other material which might form a nidus for tuberculous sputa.

The society adopted this report.

Book Reviews.

Die rationelle Behandlung der Zuckerkrankheit. Von Dr. A. Lorand, Brunnenarzt in Carlsbad. Berlin: Verlag von August Hirschwald, 1903.

As the author states in his preface, this brochure is intended for a handbook for the practical physician in his treatment of diabetics. The diet and treatment of these patients are considered, and the prophylactic régime of the children of diabetics. A short but valuable bibliography completes this little monograph.

International Clinics. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Articles on Medicine, Neurology, Surgery, Therapeutics, Obstetrics, Pediatrics, Pathology, Dermatology, Diseases of the Eye, Ear, Nose, and Throat, and Other Topics of Interest to Students and Practitioners. By Leading Members of the Medical Profession Throughout the World. Edited by Henry W. Cattell, A.M., M.D., Philadelphia. Volume III. Twelfth Series. Philadelphia: J. B. Lippincott Company, 1902.

In this issue, besides seven special therapeutic essays and the usual number of representative papers under the headings of Medicine, Surgery, Obstetrics, Gynecology, and Diseases of the Eye, Ear, and Throat, there is a special article by Borrissof on the function of the digestive glands, and a critical study of the theory of inflammation by Hans Schmaus, Cardarelli, Debore, Dieulafoy, Hallopeau, Jardine, Koenig, and Manger were among the foreign contributors, while home talent has not been inactive.

The article on insect pests of human beings, by J. J. Walsh, is noteworthy, while syphilis of the eye has been well presented by Edward Stieren. Taken all in all the volume is well up to the standard, and bespeaks no weakening on the part of the editor.

Syphilis, a Symposium. New York: E. B. Treat & Co., 1902.

This is a little work of not much over a hundred pages, still seventeen well-known names appear upon the title page as special contributors. The Etiology, by Robin; Clinical Characters, by Fournier; Unrecognized Chancre, by Gottheil; Affections of Pleura, etc., by Gwyn; of the Nervous System, by McCarthy, and of the Nose and Throat, by Gleason, are some of the features. Toward the end a series of questions have been answered by Duhring, Morton, Keyes, and others, so that their views on diagnosis, remedies, heredity, etc., can be compared. The fallacy of the advice given by many of these writers to wait for secondary manifestations before beginning treatment is shown by some of these same men who answer one of the questions with the statement that the secondary stage may be entirely skipped.

Human Anatomy, A Complete Systematic Treatise. By Various Authors, Including a Special Section on Surgical and Topographical Anatomy. Edited by Henry Morris, M.A. and M.B., Lond., F.R.C.S. Eng. Third edition, revised and enlarged. Philadelphia: P. Blakiston's Son & Co., 1902.

This complete work, which has been favorably reviewed in these columns, again appears before us. The author states that many articles have been rewritten. A large number of illustrations have been added, and many changed to color. The work is eminently practical. We read with great interest the special section on surgical anatomy. This chapter is of vital importance to the surgeon and those in search of complete knowledge of this subject. No work on anatomy is complete without ample illustrations, and the author has grasped the right spirit by elucidating page after page and chapter after chapter with numerous colored and other pictures. In all 846 illustrations add to the value of the book. To the physician or surgeon desiring to refresh his memory, and to the student learning anatomy, this work can be conscientiously recommended.

A Manual of Medicine. Edited by W. H. Allchin, M.D., Lond., F.R.C.P., F.R.S. Ed., Senior Physician and Lecturer on Clinical Medicine, Westminster Hospital. Late Examiner in Medicine in the University of London, for the Royal College of Physicians of London, and for the British and Indian Army Medical Services. Vol. IV Diseases of the Respiratory and of the Circulatory Systems. New York: The Macmillan Company; London: Macmillan & Co., Ltd., 1902.

Among the contributors to this volume we note, J. Mitchell Bruce, Francis De Haviland Hall, Leonard Hill, Hector Mackenzie, Lewis Smith, and the editor. The introductory chapter deals with the physiology of respiration, and is followed by excellent chapters on the diseases of the upper and lower respiratory tract, and of the pleuræ

and mediastinum. The latter part of the book includes the affections of the heart, the arteries, and the veins, together with an excellent chapter on œdema.

As might be expected from the writers, who are recognized authorities in Great Britain on their respective subjects, the text is thoroughly reliable, and represents the accepted teaching of their country. The book is exceptionally rich in its treatment of the physiology and the general principles which govern the dynamics of respiration and circulation. The methods of treatment are eminently sound and, considering the size of the work, are fairly complete. Quite a number of charts, sphygmographic tracings, pathological plates, and other illustrations, some of them in color, serve to enhance the value of the text. We can congratulate the editor in having issued a compact, reliable, and interesting volume on the diseases of two of the most important systems in the domain of internal medicine.

Die Erkrankungen der Nieren. By Prof. Dr. H. Senator, in Berlin. Second edition. Vienna: Alfred Hölder, 1902.

The second edition of this book appearing so soon after the first is, in itself, its best recommendation. It stands to-day as a monument in German medical literature, and represents the most advanced thought on the pathology and clinical diagnosis upon the subject of diseases of the kidneys.

The text is divided into two parts: (1) General and (2) Special. The first part treats of albuminuria and albumosuria, casts, hæmaturia, hæmoglobinuria, lipuria, chyluria, ascites, uræmia, etc.

The second part treats more especially of anomalies of the kidney, nephralgia, disturbances of the circulation and thrombosis and embolism, and the various inflammatory and degenerative processes occurring in this organ, together with a discussion upon concretions and parasitic diseases.

The articles on hæmaturia and hæmoglobinuria are of special interest, as is also the one upon the subject of ascites, in which the various theories as to its occurrence are discussed at length.

The entire practical value of cystoscopic diagnosis is only in part conceded by the author, who, in a great measure, holds himself down to diagnosis by purely clinical and laboratory methods.

Regional Minor Surgery, Describing the Treatment of Those Conditions Daily Encountered by the General Practitioner. By George G. Van Schaick, M.D., Attending Surgeon to the French Hospital, New York. New York: International Journal of Surgery Co., 1902.

This volume is offered as a guide for the performance of most of the operations of surgery which the average practitioner is called upon to undertake. Many operations are described and many conditions mentioned which cannot be classed strictly as "minor," but which are nevertheless appropriately included in a book of this character. The book is founded largely on personal experience, and almost no references are given. It has a narrow field of usefulness.

Cancers and Other Tumors of the Breast. Researches Showing Their True Seat and Cause. By Charles Creighton, M.D. Sometime Demonstrator of Anatomy, Cambridge University, etc. With 24 Lithographic Plates. London and Oxford: Williams and Norgate, 1902.

This monograph represents the painstaking labors of its writer in a subject of perennial interest to surgeons and pathologists. The author has been impressed with the fact that many so-called mammary tumors are not really new growths originating in the epithelium of the mammary gland, but are rather paramammary growths, whose origin is the epithelium of certain sweat and sebaceous glands in the region in question. This has been generally recognized, though we do not think that any definite conclusion is justifiable as to the exact proportion of such cases, nor do we think that the matter is of more than pathological interest. The present volume contains a chapter on comparative morphology of the mammary glands, and considerable interesting matter are neoplasms in animals, and there is an incidental discussion of many forms of mammary neoplasms other than carcinoma. The microscopic analysis of various mammary tumors is very minute, and results are placed before the reader in a series of very well-executed plates. Some theorizing is indulged in by the writer, but no harm is done to his collation of facts thereby, and we may consider that his work has much valuable material in it, more for the pathologist than for the surgeon. The second part of the title, which refers to the "true seat and cause" is a little misleading, and, perhaps, a little grandiloquent. His use of the word "cancer" includes many malignant and semimalignant growths, which are not actually carcinoma.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending February 14, 1903:

	Cases.	Deaths.
Measles	190	17
Diphtheria and croup	345	45
Scarlet fever	247	23
Smallpox	3	..
Varicella	135	..
Tuberculosis	282	173
Typhoid fever	37	11
Cerebrospinal meningitis	..	3

The Metric System in the United States.—In 1893 the Secretary of the Treasury ordered that the standard yard and pound should be derived from the standard meter and kilogram received from the International Bureau of Weights and Measures in Paris. The Paris standards were the most accurate possible; the ratios between yard and meter and between pound and kilo were known exactly, and it was very practical, therefore, to use the French Standards as a point of departure. The foregoing decision of the Secretary has no bearing on the question of whether French standards should be made obligatory in America. They have been permissive and legal in the United States since 1866 and they are legal in the Philippines and Porto Rico also. Whenever it is to the advantage of our merchants and manufacturers to use them, they are employed. How little real hold they have on the life of the people may be judged by asking one's friends to give the diameter of a nickel five-cent piece in centimeters, or its weight in grams. Yet this diameter was arranged to be exactly two centimeters and this weight to be five grams a considerable number of years ago. The Committee of Congress on Weights, Measures and Coinage has a bill ready that enjoins the adoption of the metric system in the United States. That system is legal now; all who are benefited by it already use it. Why force the rest of us to do what we think to be of no advantage?—*The New York Sun.*

A Curious Case of Emphysema.—G. G. Taylor reports the case of a boy of fifteen years who, while running, fell, striking the frozen ground just above his right eye. There was no sign of external injury; a few minutes later, upon vigorously blowing his nose, the right upper lid immediately bulged out, completely closing the right eye. The entire upper lid was the seat of a tense symmetrical swelling, which crepitated upon pressure. There was no sign of ecchymosis or fluid effusion. The eyeball itself appeared normal; there was no conjunctival or ciliary injection; the pupillary reflex was present and unimpaired. There was in all probability a slight fissured fracture of the antero-inferior osseous wall of the frontal sinus, without external wound. The increased intranasal tension attendant upon the vigorous blowing of the nose forced additional air up through the infundibulum and into the frontal sinus, whence a portion of it at once escaped out through the slight fissured fracture of the antero-inferior wall into the loose connective tissue beneath the skin of the upper lid, thus immediately producing an emphysema of this lid. Warm compresses and a pressure bandage were applied, and assisted in bringing about a speedy restoration, and the patient was dismissed with the injunction to refrain from blowing the nose for a week or two until the slight fissure at the point of fracture should have had opportunity to close.—*The Chicago Medical Recorder.*

Some Remarks on the Results of Tendon Transplantation in Twenty-five Cases of Infantile Paralysis of the Lower Extremity.—W. P. Montgomery concludes that the progress of cases in which the gastrocnemius and soleus

were adapted as dorsi-flexors of the ankle was very slow. Still there is no doubt that the work of re-education goes on surely, and the cases improve steadily. The greater the length of the tendon of a paralyzed muscle to which the acting muscle was applied, the less satisfactory the early result, and the slower the improvement. The results of the passive method, division of the paralyzed tendon and its suture to the intact acting one, were much inferior to those of the active method, in which a slip was taken from the normal tendon. It is better, too, to divide the paralyzed tendon and fix the graft to its cut end rather than merely to button-hole and attach the slip to the tendon in its course. There is no doubt that, at the time of the transplantation, all deformity must be corrected. As regards after-treatment, the ideal method is to begin massage and passive movement after three weeks, and gentle active movements after four. In the hospital class of patients, of course, this cannot be done, and with them it is best to fix the foot in plaster for five or six weeks, and then allow both active and passive exercises.—*The Medical Chronicle.*

A Case of Lymphadenoma Associated with Recurrent Fever.—Henry T. Bewley and J. Alfred Scott report the case of a man who came of a tuberculous family; had had mild syphilis about 1895; was quite strong till November, 1900, when a fever commenced, which lasted over five weeks, and was followed by two relapses of ten days' duration each. He was well for about six weeks, then a condition of high fever came on and lasted six weeks, ending by crisis on April 27. On May 18 pyrexia again came on, lasting till the beginning of July. Then he was well till the beginning of November, when high fever recommenced and lasted four weeks—till his death. During all this time no one could discover any cause whatever for his fever. At autopsy thoracic tumors and growths in the liver and spleen were found, made up of ovoid masses, like large lymphatic glands. Those in the thorax were composed principally of fibrous tissue strands, with a few cells lying between them. The appearances agree with those described by Greenfield as found in some cases of lymphadenoma, and is apparently the same condition called by Virchow lymphosarcoma. No microorganisms were found in any of the sections.—*The Dublin Journal of Medical Science.*

Arthritis Deformans in Children.—I. A. Abt reports a case of a form of this affection which is not frequent in children. Its causation is obscure. The joint affection is multiple, and the trouble is not confined to the smaller joints. In a large number of cases ankylosis develops, and complete disability after a period of months. Pain is a marked symptom and frequently interferes with sleep. The synovial membranes and the cartilage of the joints disappear. The ends of the bones assume ivory-like hardness and present osteophytic growths at their margins. Atrophy of the muscles follows closely upon the joint involvement. One hypothesis held in regard to the etiology of this disease is that it is due to a lesion in the central nervous system, which causes irregularity in bone growth and muscular atrophy. A second theory is the infectious origin of the disease. The treatment which is advised in these cases is that the children should be placed upon iodide, and, when possible, removed to a warmer climate. In any event, the conditions of hygiene should be improved.—*The Wisconsin Medical Journal.*

Aortic Aneurysm Treated by Electrolysis.—H. A. Hare reports a case, and the conclusions which he reaches are as follows: Electrolysis, in properly-selected cases of aneurysm, is a valuable measure, and prolongs life. The operation itself is neither dangerous nor painful. The failure of permanent cure does not depend so much upon the failure of the operation to limit the disease locally as on the fact that the adjacent parts of the blood vessel are weak and, when the most bulging area is solidified by the clot, these lateral areas may later on give way. Even in these cases life is prolonged by the closing of the weakest area, and it is not to be forgotten that in at least one case (Stewart's) life was prolonged three years, death taking place from an alcoholic debauch.—*Proceedings of the Philadelphia County Medical Society.*

A Case Illustrating the Neglected Results of Infantile Paralysis and the Treatment.—S. W. Kelley describes the case of a boy of five years, who had suffered from paralysis when a year old, and had received no treatment for the results. His lower extremities were thin and weak, and unable to support the weight of the body in a normal position. The left thigh could not be more than half extended. Such contraction and deformity would not occur if limbs were placed and held in position to be used as soon as the stress of the attack is over. And if massage, with stimulating oils and lotions, and (when all inflammatory symptoms had subsided) electricity be used, the feeble circulation, the atrophy, and weak contractility of muscles will seldom proceed to an extreme degree. In the case reported, the author released the contracted tendons of the thigh, and also the tendo Achilles by tenotomies, and applied braces, after which active exercise, supplemented by hot bathing and massage for several weeks, began to develop and increase the strength of the limb. The boy can now walk fairly well.

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ending February 14, 1903:

REMARKS ON ACHYLIA GASTRICA AND PERNICIOUS ANÆMIA.

BY MAX EINHORN, M.D.,
NEW YORK.

PROFESSOR OF MEDICINE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

THE clinical pictures of achylia gastrica (formerly called atrophy of the stomach) and of pernicious anæmia are of recent origin. Both conditions are frequently found together, and many writers have pointed out not only the intimate connection of both diseases, but have considered both as nearly identical by assuming that the atrophy of the gastric mucous membrane was the cause of the pernicious anæmia.

The final decision on this question has not yet been given; besides, there are a good many other problems in achylia gastrica awaiting solutions. Under these circumstances it seemed to me advisable to touch upon both subjects in one paper and add my mite toward the elucidation of several points.

Achylia Gastrica.—I first desire to relate my experience regarding several new points in achylia gastrica, which have been as yet somewhat uncertain.

Achylia Gastrica with Return to the Normal State of Secretion.—Achylia gastrica is an obstinate affection. Until recently it was not known whether a return to the normal stomach secretion can take place. I myself[1] have published one case, in which a return of the normal secretion occurred. Other authors also have observed similar cases. Such an occurrence, however, is certainly rare. I, therefore, wish to describe three more new cases belonging to this category, in which achylia gastrica returns to normal secretory activity.

CASE I.—January, 1898. Arthur C., twenty-three years old, complains for the last two years of a great deal of belching, poor appetite, constipation, and frequent vertigo. For the latter condition he has been treated by ear- and eye-specialists at various times, but always without success. Physical examination does not reveal anything abnormal in the thoracic organs; the abdominal organs also are negative on palpation. The stomach lies in its normal position, the larger curvature reaching to within two finger's breadth above the navel. Examination of the stomach contents one hour after test-breakfast shows: HCl=O; acidity=2; no rennet, no pepsin; very little fluid, particles of roll not changed. The patient was treated for some time with direct faradism of the stomach. His condition improved, the attacks of vertigo disappeared; still the condition of the stomach in regard to its secretion remained the same throughout the entire year of 1898–1899. A new examination of the stomach contents in 1900 showed the following: HCl+, acidity=40, rennet+, pieces of roll finely subdivided, amount of fluid more than half. Thereafter a similar condition of the stomach relative to its secretion was often found.

CASE II.—December, 1899. John G. M., fifty-two years old, complains of frequent eructations, capricious appetite, tired feeling, and frequent diarrhœa. The patient has lost ten pounds in weight during the last year. Physical examination of the thoracic organs reveals nothing abnormal. Examination of the stomach contents one hour after test-breakfast, December 18, 1899, shows: HCl=O; reaction, neutral, rennet=O, pieces of roll unchanged, only traces of fluid present. A similar result was obtained in April, September, and November, 1899, as well as January and April, 1900. On December 28, 1900, however, one hour after test-breakfast, the following results were obtained: HCl+; acidity=36; rennet+; two-thirds of the contents are formed by liquid; pieces of roll finely subdivided. On October 15, 1902, a new examination of the stomach contents demonstrated the presence of HCl, of rennet, and an acidity of 40; pieces of roll are finely subdivided. The patient's general condition was decidedly improved; a tendency to diarrhœa, however, remained.

CASE III.—February, 1898. Mrs. Margaretha D., about forty-three years of age, complains for the last few years of digestive disturbances; her appetite is usually poor, after eating a sense of fulness results, accompanied by frequent eructations, and the bowels are constipated. With the exception of the stomach, which contained absolutely no secretion, the various organs are normal. During 1898-1899 the examination of the stomach contents always gave the same result: HCl=O; acidity fluctuating between 2-6, no ferments, very little fluid, pieces of bread hardly changed. In 1900, and later, a normal stomach secretion was always present.

Abrupt Development of Achylia Gastrica in Pronounced Cases of Hyperchlorhydria and, after the Achylia Has Persisted for Years, Return to the Normal Secretion.—The etiology of achylia gastrica has not yet been definitely established. Biedert[2] and Martius[3] do not think it impossible that we have to deal here with a congenital defect. My opinion, that in achylia gastrica we have to deal with purely nervous conditions, is rejected by Martius in the following words: "I must confess that I cannot do much with this assumption. In 'irritable weakness' of the nervous system there is a tendency to abnormal increase of the function, followed by rapid exhaustion. In a typical case of gravest neurasthenia, which I published elsewhere, hypersecretion of the gastric juice was present, which suddenly turned into a temporary, almost complete, cessation of stomach secretion. A continuous and uninterrupted inhibition of a normal function for months or years on a neurasthenic basis is, so far as I know, without analogy. With the designation "purely nervous" we can do here still less than anywhere else."

The following three observations which I have collected during the course of many years show very plainly that such a complete inhibition of secretion for years is certainly possible.

CASE I.—November, 1894. Edward D., forty-two years old, was suffering in 1894 from severe digestive disturbances (pains two hours after eating, pyrosis and constipation) and lost over forty pounds in weight. When I examined him in September,

1894, I found a marked dilatation (atony) of the stomach and hyperchlorhydria. Examination of the stomach contents one hour after a test-breakfast showed the presence of HCl and an acidity of 88, no food remnants from the day before. The patient was then treated with alkalies as usual, intragastric faradization was used besides. In the course of the winter of 1894-1895 the subjective symptoms of the patient improved considerably, although the stomach secretion showed more or less hyperchlorhydria all the time. His state of nutrition was much better and the patient gained considerably in weight. In April, 1895, a renewed examination of the stomach contents one hour after Ewald-Boas's test-breakfast gave the following results: HCl=O; acidity=4; rennet=O; pieces of roll nearly unchanged; very little fluid. During the next four years the patient was examined two to three times a year as to his stomach secretion: there was always a complete absence of gastric juice. Twice small pieces of stomach mucous membrane were found in the stomach contents; a microscopical examination showed that most glands were very small. During all these four years he felt perfectly well, could eat plain ordinary food, and never complained of his stomach. Only occasionally he complained of a light attack of diarrhœa with mucus in the stool. Besides he had a few symptoms of neurasthenia, as, for instance, lack of sleep after trifling excitement, temperary impotence, etc. During the entire period of four years, therefore, a complete typical achylia was present. In 1900 the examination of the stomach contents after test-breakfast showed unexpectedly perfectly normal conditions, HCl+; acidity=40; total contents removed 100 c.c.; of which over half was fluid; pieces of roll finely subdivided. From then until the present time the gastric secretion (as often as examined) was found to be normal. Otherwise no change could be observed in the condition of the patient; the neurasthenia, as well as the occasional attacks of diarrhœa, remained the same.

Case II.—February, 1895. Morris J., fifty-four years old, has been suffering since youth from occasional attacks of diarrhœa, otherwise his health was always good. For the last six years he complained constantly of severe burning sensations in the pit of the stomach, occurring one to two hours after meals. The patient has lost thirty pounds during the last two years and feels rather weak and miserable. Examination of the patient in the middle of February, 1895, revealed no morbid changes in the thoracic organs; a high degree of enteroptosis was, however, present; the stomach was low, small curvature somewhat above the navel, large curvature reaching to the pubis, right kidney movable in third degree. On the 20th of February, 1895, the stomach contents were examined one hour after Ewald's test-breakfast, and showed the presence of HCl and an acidity of 86. The urine contained neither sugar nor albumin. It was, therefore, a case of enteroptosis and hyperchlorhydria. The patient was told to wear an abdominal supporter and received a half teaspoonful of bicarbonate of soda three times daily, two hours after meals. The condition of the patient improved visibly; he soon was rid of all his complaints and gained considerably in weight. In October, 1895, he looked well nourished, and an examination of the stomach contents still showed hyperchlorhydria. For two years he disappeared from my observation and consulted me again in October, 1897. He told me that during that time he had felt well, but that lately his appetite was rather capricious and that he had to urinate frequently. Examination of the stomach contents one hour after test-breakfast showed the following condition: HCl=O; acidity=4; no rennet; little fluid; pieces of roll unchanged. From the years 1897 until 1900 frequently repeated examinations of the stomach contents always showed a complete achylia gastrica. Since October, 1900, gastric secretion with free HCl, in normal amount, was again found, without any marked change in the condition of the patient having occurred. This normal secretion of the stomach juice is still present in the patient, and his only complaint refers to a capricious appetite, frequent urination, and occasional diarrhœa.

Case III.—May, 1896. Charles P., forty-three years old, suffered for the last two years from severe, frequently recurring attacks of abdominal pains and vomiting, necessitating morphine injections. In the interval the patient complained also of a feeling of discomfort about two hours after meals and constipation. He had lost during his illness fifty pounds in weight. A careful examination shows only the presence of hyperchlorhydria. May 14, 1896, one hour after test-breakfast, HCl was found present with a total acidity of 90; no food from the day before. Patient was treated with alkalies and put upon a liberal diet. His condition improved, although hyperchlorhydria was again found present in the stomach contents in September, 1896. In February, 1897, examination of the stomach contents one hour after a test-breakfast showed the absence of HCl; an acidity of 4; no rennet; little fluid; pieces of roll hardly changed. The patient felt perfectly well, had no disturbances whatsoever, and had gained thirty pounds in the meantime. From then on he continued to feel well and to gain in weight. Analysis of the stomach contents during the next two years showed an absolute achylia gastrica. In 1900, however, normal gastric juice was found again, which has persisted until now. The patient is in the best of health; he had gained since the beginning of his trouble seventy pounds, and I had to instruct him how to avoid becoming still stouter.

These cases cannot be compared with nervous dyspepsia or gastric neurasthenia, in which a varying condition of the stomach secretion is present. For in nervous dyspepsia the clinical picture is the same, and the secretion changes sometimes every week or even every day. In our cases, however, the existing anomaly is a condition present for months, even for years, accompanied usually by the symptoms peculiar to it; if a change in the secretion takes place it is a lasting one and the old symptoms disappear with it.

Idiopathic and Secondary Achylia Gastrica.—When I chose the name of achylia gastrica I especially emphasized that it should embrace all conditions in which constant lack of gastric secretion was found during a long period of time. Whether this condition is due to an atrophy of the stomach mucous membrane is difficult to determine during life and of subordinate significance. The distinction between idiopathic achylia or achylia gastrica simplex and secondary achylia, based upon an atrophy of the glands of the stomach, as Martius desires it, does not seem to me to be specially serviceable, as, on the one hand, the so-called idiopathic achylia gastrica can certainly cause atrophy of the stomach glands; on the other hand a grave, so-called secondary achylia, with severe anæmic symptoms, can occasionally recover. There is, thus, during life no fundamental difference, and we can, therefore, designate the cases simply as either light or severe.

Cases of carcinoma of the stomach with achylia are sometimes observed. Whether the cancer causes the achylia or not is difficult to decide.

It might just as well be assumed that the carcinoma has developed in a patient with achylia, unless

we are informed of the previous state of the gastric secretion and found it active in digestive power. The distinction between pure achylia gastrica and that connected with carcinoma is, indeed, sometimes very difficult. Prolonged observation of the patient, however, will decide the question whether carcinoma is present or not. It is of utmost importance to know the state of the stomach in the fasting condition. In achylia gastrica it is completely empty; in cancer, however, some food remnants will frequently be found. In cancer the acidity of the contents one hour after test-breakfast is usually higher, although there are exceptions. Small hemorrhages in washing the stomach are also usually more often found in carcinoma than in pure achylia gastrica. The presence of a tumor would, of course, soon clear the situation; but even without it our attention will be directed toward the malignant nature of the trouble by the unsuccessful result obtained by any dietetic or therapeutic measures. The cases of carcinoma complicated with achylia gastrica in which the diagnosis is difficult are certainly rare. I, myself, have observed two cases in which a decision of the question could not be reached for several weeks.

Pieces of Gastric Mucous Membrane.—Martius believes that the occurrence of pieces of mucous membrane in the stomach contents or in the wash water from the stomach is especially characteristic of patients with achylia. I must own that this phenomenon may frequently be observed in achylia, but I have seen a great number of patients with achylia in whom pieces of mucous membrane were never obtained.

Condition of the Blood in Achylia Gastrica.—In a large number of cases of achylia gastrica I had the blood examined by my assistant, Dr. G. L. Laporte. The results obtained are embodied in the accompanying table:

TABLE SHOWING THE CONDITION OF THE BLOOD IN CASES OF ACHYLIA GASTRICA.

No.	Name.	Age.	Hæmoglobin.	Red blood-cells.	White blood-cells.	Remarks.
1	M. A.	30	100%	4,235,000	5,700	
2	T. B.	50	100%	5,290,000	6,200	
3	F. J.	25	100%	4,580,000	7,600	
4	Miss Sch.	35	90%	4,650,000	8,200	
5	P.	46	87%	4,850,000	8,000	
6	Dr. G. McL.	50	82%	4,890,000	9,800	
7	Dr. A.	50	82%	4,450,000	6,600	
8	G.	52	82%	5,330,000	8,660	
9	F.	38	81%	5,211,000	9,600	
10	Dr. T. G. W.	50	77%	5,650,000	8,500	
11	S. F.	54	70%	4,620,000	8,600	
12	Dr. J. C. R.	45	58%	2,360,000	12,500	Red blood-cells somewhat anæmic and pale.
13	Dr. S.	40	52%	2,604,000	4,800	Moderate poikilocytosis. Majority of red blood-corpuscles normal. Occasionally polychromatophilic red blood-cells.
14	Mrs R.	55	45%	1,536,000	4,400	Poikilocytosis. Normocytic type.
15	H. G.	40	41%	3,720,000	28,500	Normal red blood-corpuscles alternate with such in which the biconcavity is large and pale. No poikilocytosis. No megalocytes.

In eleven cases the blood was about normal, in only four of the fifteen cases examined a reduction of the blood-corpuscles was found. This was most marked in case XIV, in which there was, besides, a relatively large amount of hæmoglobin with marked poikilocytosis; the blood picture, therefore, showed several characteristic signs of pernicious anæmia. The other three cases (12, 13, 15) showed merely a marked anæmia.

Pernicious Anæmia.—Under the term pernicious anæmia, as is well known, a condition is understood in which a considerable reduction of the blood takes place, and in which the patients usually die by gradual loss of strength without any demonstrable organic lesion of the body. Biermer[5] was one of the first to describe this disease more accurately, and has detailed the clinical symptoms as well as the results of autopsy. Biermer enumerated the following symptoms, as usually met with in this disease:

(1) Anæmic-hydræmic appearance, great paleness, but no atrophy of the panniculus adiposus, yellowish white appearance of face, later œdematous swelling of the face and the extremities; (2) weakness, vertigo; (3) digestive disturbances; (4) circulatory disturbances, murmurs in heart and vessels; (5) fever, slight and irregular; (6) apoplexies of the retina; (7) hemorrhages in the skin (small petechiæ) not frequently present; (8) apoplexies in the capillaries of the brain have frequently been found on autopsy, without having caused symptoms during life.

According to the same author, the course of pernicious anæmia is as follows: "gradual increase of the anæmia and hydræmia, accentuation of the heart symptoms, accidental capillary hemorrhages, hydræmic transudations, some fever, subsequent anorexia, frequently diarrhœa, fatal result in nearly all the cases, except one that was cured."

On autopsy Biermer found universal anæmia, nearly always partial fatty degeneration of the papillary muscles and the small vessels. Liver, spleen, and kidneys showed nothing abnormal.

Quincke[6] somewhat later also described a few cases of pernicious anæmia, and laid special stress upon the following points as of etiological moment: direct loss of blood, great exertions, the puerperal state, lactation, diarrhœa. Quincke also called attention to the connection of dyspepsia and pernicious anæmia. He expresses himself in the following manner: "Dyspepsia and diarrhœa once present, are kept up by the uniform insufficient nutrition; several times both disappeared on entering the hospital, merely through the change of diet."

This clinician was also the first, who carefully examined the blood in pernicious anæmia. He found that the blood had the following characteristics: poikilocytosis; among red blood-corpuscles of normal size (6 mikra) many microcytes of 4-1 mikra, as well as occasional macrocytes, are found. The white bood-corpuscles were increased only once. Mononuclear, colorless masses were more often present. According to Quincke, however, pernicious anæmia is not to be separated from ordinary anæmia; there is a difference of degree only, but not of principle. According to this writer, the prognosis of pernicious anæmia is not so absolutely fatal as Biermer and others maintained; it is, however, still bad enough, for, according to him, over half of the cases die.

Several more recent authors attempted to find in the blood itself signs characteristic of pernicious anæmia. According to them, the amount of hæmoglobin ought to be larger than would correspond to the number of red blood-corpuscles. There would, therefore, be present in each individual corpuscle an excess of hæmoglobin. Furthermore, megaloblasts will be found here and there. These signs are, however, not recognized by many clinicians as particularly necessary to the picture of pernicious

anæmia. Grawitz[1], among the hæmatologists, also inclines to this view.

I have taken the liberty to adduce these facts regarding pernicious anæmia, in order to show that, even at present, the clinical symptoms, as described by Biermer, are the most important factor in recognizing this disease. I have observed several cases of pernicious anæmia in the sense of Biermer and Quincke, and will describe only those in which an examination of the stomach contents has been made.

Case I.—March, 1893. George S., fifty-eight years old, is suffering for the last eight months with pains one-half to one hour after meals. The appetite is capricious, bowels are usually constipated, and sleep is somewhat impaired. The patient has lost only a few pounds, but feels very weak; the least bodily exertion soon produces a feeling of weariness, so that the patient can walk only short distances.

Present Condition.—Color of lips and cheeks pale, anæmic. Tongue not coated, panniculus adiposus well preserved. In the chest organs nothing abnormal. Palpation of the abdomen shows tenderness on pressure in the epigastric region. In the region of the stomach a splashing sound can be produced only with difficulty; the large curvature seems to lie about two fingers' width below the navel.

The stomach contents examined one hour after test-breakfast show: HCl+; acidity=46; rennet+. The urine contains neither sugar nor albumin. Knee reflexes are normal. The blood shows a high degree of poikilocytosis; mikro and megalocytes and apparently no increase of white blood-cells. The diagnosis was at that time made of pernicious anæmia and hyperæsthesia of the stomach.

Patient was treated for some time with intragastric galvanization, which seemed to allay the pains in the stomach somewhat. The treatment otherwise consisted in suitable nutrition and the administration of peptonate of iron and at times of arsenic. The condition of the patient, however, did not seem to improve, and his strength gradually decreased.

In the summer of 1893 he went to the country, where he had better care and better food. But even here he did not feel better; severe attacks of diarrhœa developed, which soon yielded to treatment, but left the patient much weaker. In August a renewed examination of the stomach contents showed the presence of free HCl. In September the patient became so weak that he had to stay in bed constantly; he suffered frequently from fainting spells and complained much of pain in the stomach.

In October, 1893, without there having been any considerable emaciation, the patient died from the effects of increasing weakness in a comatose state. An autopsy was not permitted.

Case II.—November 24, 1900.—Jacob B., forty-seven years old, coachman. His father had suffered much from nose-bleed and died of some stomach trouble. The mother is still alive and well. Family history is otherwise negative. Patient has complained even from childhood of nose-bleed (brother and sister have also had it as well as his four boys). Twenty-five years ago while in the army he has had an ulcer in the stomach. Since then he has had rheumatism once, eleven years ago. Up to three years ago patient was always healthy, with the exception of an occasional nose-bleed. The latter at that time became worse (two to three times daily), and shortness of breath developed. He was unable to work any more and is unable to do so now.

Bowels are regular, appetite is good, sleeps well, but has a headache if he has no bleeding from the nose. As soon as the latter occurs, his headache leaves him. He complains of pains over the heart region. He has not lost in weight.

Present Condition.—Man of medium size, color of face pale, yellowish; numerous petechiæ on the lower lip, less on the upper lip, one on the right conjunctival mucous membrane, about twelve on the anterior surface of the chest, four to five on the back. Boundaries of heart somewhat enlarged to right; at the apex a light systolic murmur. Lungs normal, spleen somewhat enlarged, reaching to within a finger of the costal margin, liver projects one finger's width over free margin of ribs.

Urine negative, examination of the stomach contents one hour after test-breakfast: HCl+; free HCl=68; total acidity=88. First swallowing sound two seconds, second swallowing sound nine seconds after drinking of water. Hæmoglobin 20 per cent, red blood-corpuscles 1,824,000, leucocytes 3,600. Marked poikilocytosis. Some few normoblasts.

Case III.—May 21, 1901.—Sam R., forty-seven years old, a saddler by occupation, had typhoid fever with pneumonia fifteen years ago. He was then very sick and was in bed for seventeen weeks. He entirely recovered from this. Twelve years ago he came to the United States and has never been ill until a year ago, when he had chills and fever. Under medical treatment he was well again in a week. He then went back to work and has never had fever since. About eight months ago he began to complain of pains in the stomach, which occurred before as well as after eating. Usually they were most intense two to three hours after meals, lasting about one-half to two hours. A feeling of nausea was also frequently present. His appetite was always good as well as his sleep; he complained, however, of vertigo, headache, and constipation. His color gradually became paler and paler. He claims never to have vomited blood nor passed any in his stool. Twice, however, during the last eight months hemorrhoids emerged from the rectum, and he then noticed a little blood in the stool. Occasionally his legs begin to swell. Lately he does not sleep so well. He has lost about seven pounds. Upon the advice of a physician he has been fed per rectum for about three days, receiving nothing per os, but his gastric pains did not abate.

Present Condition.—Patient looks exceedingly pale, lips hardly show a trace of red. The lobes of the ears are also very pale, with a somewhat yellowish tinge. Tongue not heavily coated. Knee reflexes present. Panniculus adiposus is well preserved. Thoracic organs: at the apex of the heart a soft presystolic murmur is heard. Heart dulness is not enlarged. There is nothing abnormal in the lungs. Abdominal organs: dulness of liver and spleen is normal. To the left of the linea alba, somewhat below the ensiform process, a small hernia of the size of an egg is visible, which can be replaced easily. The stomach extends to about one to two fingers above the navel. The epigastric region is somewhat tender on pressure, otherwise nothing abnormal can be demonstrated in the abdomen by palpation. The urine contains no albumin, no sugar, specific gravity 1012. Microscopically, only a few leucocytes are found. The examination of the blood shows hæmoglobin 30 per cent., red blood-corpuscles 3,680,000, white blood-corpuscles 10,200. In the stained specimen the principal characteristics are the small amount of hæmoglobin and the poikilocytosis of the red cells. Polychromatophile degeneration is present in a small degree. The diameter of the erythrocytes in the majority of cases is normal (about 7½ mikra); in a few only 8-10 mikra and none above ten mikra. Normoblasts or megaloblasts are not present.

A differential count of 300 leucocytes shows the following percentages: polymorphonuclear, 78; small

lymphocytes, 12; large lymphocytes, 7; transitional forms, 0.6; eosinophiles, 1.4; mast-cells, 1.

Although the blood picture in case III was not typical of pernicious anæmia, yet the clinical symptoms were so marked that I was unable to interpret the present disease otherwise than that of pernicious anæmia.

Is There Any Connection between Achylia Gastrica and Pernicious Anæmia?—As Hemmeter[8] and Welch[9] correctly say, Austin Flint [10] was the first to think of a connection between grave anæmias and atrophy of the stomach mucous membrane. In 1860 Flint said the following: "Of the importance of the stomach glands we can form an estimate when we consider that their business is to furnish from fifteen to thirty pounds of gastric juice during the twenty-four hours. Nor is it difficult to see how fatal anæmia must follow an amount of degenerative disease, reducing the amount of gastric juice so far that the assimilation of food is rendered wholly inadequate to the wants of the body. I shall be ready to claim the merit of this idea when the difficult and laborious researches of some one have shown it to be correct."

In 1871 Flint described four cases, which died of inanition. Clinically it was impossible to demonstrate any change in any of the organs. Autopsies were not permitted. He expressed himself as follows: "I have for many years had a strong conviction that the secretory glands of the alimentary canal constitute a territory in pathology, until now almost a *terra incognita*, whence are to be derived very important additions to our knowledge of disease. It has seemed to me a rational supposition that destructive lesions of these glands exist in a class of cases characterized by progressive and fatal inanition taking place without the evidence of disease existing elsewhere sufficiently to explain the symptoms and the termination. I have long been accustomed in lectures and consultations, as also in published writings, to predict that in the cases now referred to, the tubules of the alimentary canal will be found to be the seat of degenerative changes, which, in view of the important functions of these glands, will account satisfactorily for the symptomatic phenomena and death." Flint himself did not follow up the histology of the stomach any further, but refers to the investigations of Handfield Jones, Wilson Fox, and S. Fenwick.

Fenwick[12] was the first to notice the fact that in patients who had died of pernicious anæmia a marked atrophy of the stomach mucous membrane was found. The result of the autopsy caused him to assume the atrophy of the gastric mucous membrane as the original cause of the pernicious anæmia. Fenwick's doctrine was subsequently accepted by several clinicians, Henry and Osler[13], Nothnagel[14], Kinnicutt[15], Von Kahlden[16], and others, who observed similar cases. More recent writers, however, are not of the opinion that pernicious anæmia is caused by the atrophy of the stomach.

Neusser[17] has examined the metabolism in a case of gastric atrophy with pernicious anæmia. He arrives at the result that there were at least some cases of pernicious anæmia with atrophy of the glands of the stomach in which the albumin metabolism took place in exactly the same manner as in healthy adults. The opinion of some authors that the severe anæmia in these cases is the result of malassimilation of the food is therefore not correct. On the contrary, he found in his case that even in severe pernicious anæmia complicated with stomach atrophy the power of the body to utilize nitrogenous material of the food responds even to large demands made upon it.

. Strauss[18] also is of a similar opinion. He says: "The facts brought forward in this paper permit us to maintain now even more energetically than formerly the view that at present we have not sufficient positive proof to allow us to raise the idea—that the atrophy of the stomach and intestine may cause pernicious anæmia—above the level of a hypothesis, the admissibility of which, as applied in the present time, still needs considerable corroboration. . . . Therefore, we are much more inclined, especially in view of the results communicated in this paper, to look upon the functional and anatomical changes of the digestive tract, as a coördinated phenomenon, or perhaps even a subsequent result of pernicious anæmia rather than as a cause of this disease."

In 1892 I[19] voiced my doubt of the correctness of Fenwick's doctrine in the following words: "If the authors mentioned conclude from the post-mortem findings (atrophy of the gastric mucous membrane) that the disease of the stomach is the fundamental cause of the trouble, *i. e.* the anæmia, it is possible that this may be true, but it has not by any means been proven. First, the evidence is lacking that in all cases of pernicious anæmia an atrophy of the stomach mucous membrane is found; secondly, not all cases of atrophy of the stomach show the symptoms of pernicious anæmia. Perhaps the atrophy of the stomach in these cases is caused by the bad state of nutrition due to the pernicious anæmia?"

My own present observations also speak against the assumption that pernicious anæmia is caused by atrophy of the stomach for the following reasons:

1. In most cases of achylia gastrica a nearly normal condition of the blood is found.

In one case of achylia gastrica[20] in which at autopsy a total atrophy of the stomach mucous membrane was found, pernicious anæmia did not exist during life.

2. We occasionally observe the presence of gastric juice in cases of pernicious anæmia, sometimes even in an increased amount, as is evident from the three cases reported above. If pernicious anæmia were caused by an atrophy of the gastric mucous membrane, the achylia would have to be well marked, as soon as the symptoms of the blood disease are apparent.

We cannot deny that achylia and pernicious anæmia may occur together. These cases are, however, in the minority, and would probably point to the fact that there is a common cause for both affections, or that pernicious anæmia finds a ready soil in cases of achylia. We must also think of the possibility that in grave cases of anæmia (pernicious anæmia) in the last stages of the disease, changes may occur in the stomach and intestinal glands (atrophy) just the same as analogous changes in the spinal cord have been observed in this disease.

RECENT RESEARCHES ON THE VOICE.*

By PROF. E. W. SCRIPTURE,
YALE UNIVERSITY.

Within the last ten years a new science has been gradually developing. This science of "experimental phonetics" comprises several main departments of investigation, such as the study of the movements of the vocal organs in producing speech

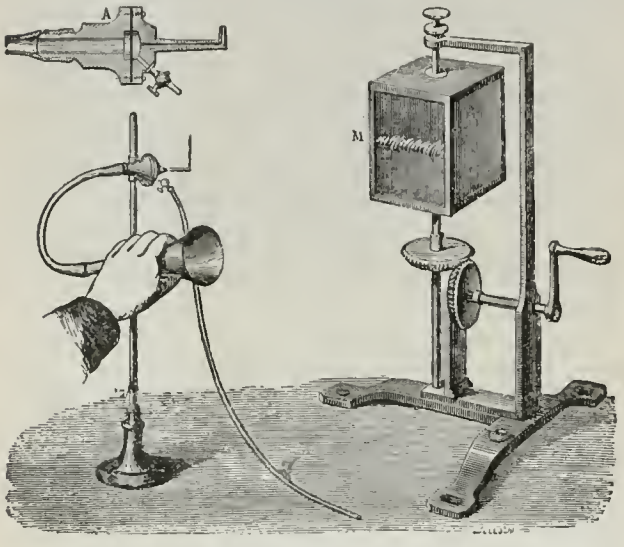

Fig. 1.

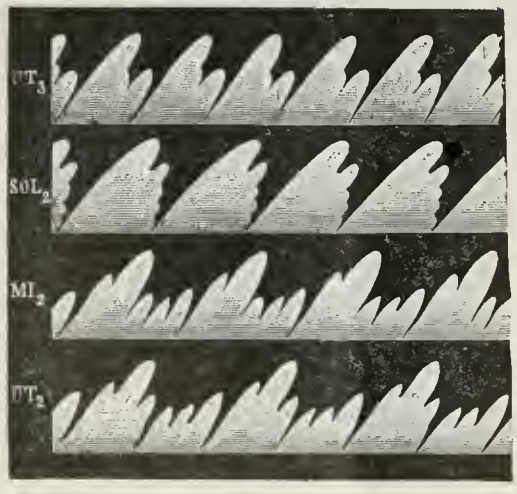

Fig. 2.

sounds, the associations of ideas as the basis of grammar and of language teaching, etc. Here I wish to speak of one special department only, namely, the study of speech curves and the deductions to be drawn from them. The first machine for recording speech was devised by Scott of Paris, who, as a proofreader, got his suggestion from a picture of the ear. Several other phonoautographs were afterward invented; in all of them a diaphragm of rubber, gold-beaters' skin, ivory, etc., moved a lever which recorded the vibrations on a moving surface. Some of these instruments probably give quite accurate tracings of the vibrations of the air from the voice, but the method suffers from the fact that the tracings cannot be turned back into speech.

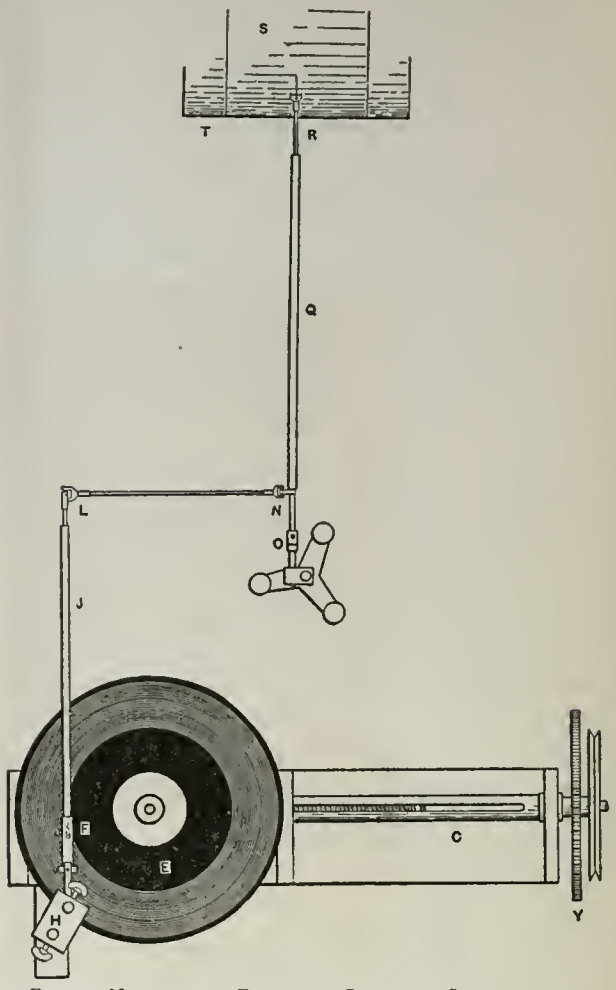

Fig. 3.—Machine for Enlarging Curves of Speech from a Gramophone Plate.

E, gramophone disk with spiral speech-groove containing lateral vibrations; *C*, revolving barrel with feed-screw that turns the disk and moves it sidewise; *Y*, gear-wheel that turns *C*, being moved by the last of a series of reducing-gears connected to a motor; *J*, magnifying lever containing a fine steel point near *F*, which travels in the speech groove and follows its vibrations; *L*, *N*, gimbal joints with connecting-rods that transmits the movements of *J* to the second lever *Q*; *O*, fulcrum of *Q*; *R*, recording-point that draws a line on a slowly moving band of smoked paper *S*; *T*, side of one of two cylinders about 8 feet apart, around which the band of smoked paper travels. The movement of the point in the speech-record at *F* is repeated with great magnification by *R* and recorded as a white line in the soot

A very novel method is that invented by Koenig of Paris. A current of gas is conveyed to a small chamber, from which it issues through a fine jet and burns as a little flame. The back wall of the chamber is formed of a rubber membrane. The speaking tube leads to this membrane, and the vibrations of the voice set it in movement. The flame when viewed in a revolving mirror shows the vibrations. A view of the apparatus is shown in Fig. 1; some results are given in Fig. 2.

The most reliable method at the present time consists in first getting a satisfactory record on a talking-machine, and then tracing off the curve; the record itself and the results can be tested and verified by listening to the speech as reproduced by the machine. The best phonographs and gramophones now pro-

*Summary of a lecture before the Brooklyn Medical Club. Figures 1 to 3 are from Scripture's "Experimental Phonetics" (Yale Bicentennial series); Figure 4 is from the *Century Magazine*.

duce records that hardly fall short of perfection. It remains only to devise machines that will trace off the records on to paper so that they can be studied with accuracy.

For tracing off the curves of a phonograph cylinder a very accurate machine has been devised by Professor Hermann of Koenigsberg. A fine glass point runs in the groove cut in the wax, and moves a system of small levers, which reflect a beam of light. The light is made to record its movements on a sensitive band of paper. The curves are of great accuracy and beauty.

For my own work I use two methods. With one method I obtain a gramophone or a zonophone plate with the desired material on it. The plates made for printing. One such block, showing words spoken by Joseph Jefferson, is shown in Plate I.

Let me give an illustration of the way in which such curves are studied. Take, for example, the word "So," the second line of Fig. 4. The vibrations are seen to be in groups of fairly similar character; each of these groups we know to represent one vibration of the vocal cords with the vibrations of the vocal cavities imposed upon it. The time of each vibration of the cords is found by measuring the length of each group. In this way we can get the melody on which the vowel is spoken. The melody for the entire toast by Jefferson has thus been calculated.

The curves also give the tones of the vocal cavities.

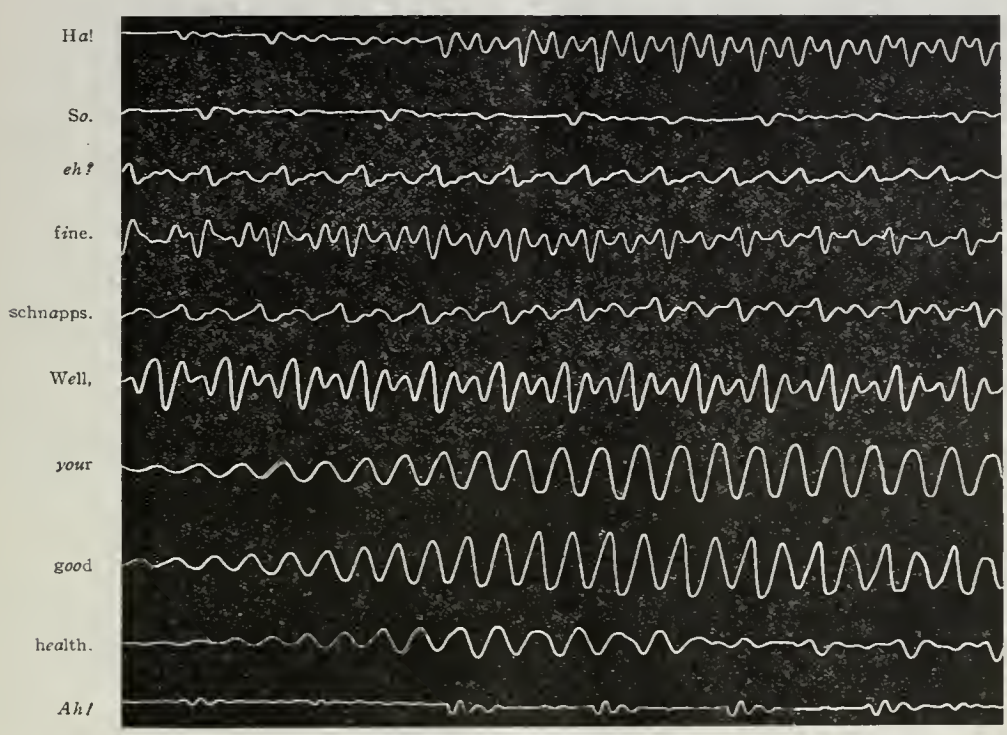

Fig. 4.—Curves from the Voice of Mr. Joseph Jefferson in "Rip Van Winkle's Toast."

The first line shows the beginning of the *a* in the exclamation "Ha!"; the vibrations are in groups, as explained for Figure 1; there is a quick rise of intensity (indicated by the vertical extent of the vibrations) and a slow rise in pitch (indicated by the horizontal length of the groups); the strong vibration found in the middle of each group is peculiarly prominent in Mr. Jefferson's voice; it probably indicates a strong resonance from the chest. The second line is a portion of *o* in "So"; it is a soft, even sound of falling pitch; there are ten groups of vibrations, indicating ten vibrations from the vocal chords; but the alternate groups are slightly different, indicating some interference with their action that produces a peculiar rumbling modulation expressive of satisfaction. The third line is a portion of *e* in "eh?"; its pitch (indicated by the length of the groups) is higher than in the previous examples. The fourth line gives a piece of the *a* sound contained in *i* of "fine"; the resemblance to the *a* in "Ha!" is very close (no two sounds are exactly alike); it differs from *a* in Figure 2 chiefly in having the large intermediate vibration (indicating the strong chest tone) and in the greater evenness of the vibrations within each group (indicating a smoother explosion from the vocal cords). The fifth line gives a portion of the vowel in "schnapps"; there is some resemblance to the vowel of "eh?" The sixth line is a piece of the vowel in "Well"; it is quite loud; the pitch is nearly steady. The seventh line gives the end of *y* and the beginning of *ou* in "your"; the *y* is weak; the *ou* is loud; in *ou* the alternate vibrations are stronger, indicating two vibrations of the mouth cavity to each explosion from the cords. The eighth line contains the beginning of the vowel of "good" as the mouth-passage opens after the *g*; the portion in the middle of the line resembles the *ou* of "your," but the vowel steadily changes its nature. The ninth line gives the first part of the vowel in "health." The last line is the beginning of the exclamation of satisfaction "A-ah!" with which the "Toast" ends; it is of steadily falling pitch; the last part of our record of this sound shows vibrations of such low pitch that the ear cannot hear them.

according to the new processes leave nothing to be desired. The former scratchiness of gramophone plate has practically disappeared, and the records are reproduced with an accuracy of intonation that is practically perfect. With another method I obtain phonograph cylinders in celluloid from a company in Paris.

To trace off the curves from the gramophone plate I place it on a special machine, of which the top view is shown in Fig. 3. The gramophone plate is rotated at a speed of about once in five hours. The vibrations are reproduced with great enlargement on a moving band of paper covered with smoke. The speech line appears as a white curve on a black surface. The record is varnished; the speech curve is cut out of it and reproduced in the form of blocks

We notice in the first place that the speech vibrations are not like those of stringed instruments or of curves produced by adding a series of simple harmonic curves. The curves of the voice are such as can be produced only by a sudden blow on a cavity. The blow is that of an explosion from the vocal cords. The cords close and obstruct the air; the pressure forces them apart for an instant, and they again close. With a steady pressure this produces a series of puffs like that from a disk with holes passed before a jet of air. Such a disk—the familiar "siren" of the laboratory—gives a tone whose pitch depends on the number of holes passing before the jet. The cords act in an exactly similar manner to emit a series of puffs which is heard as the tone of voice.

But how are the cavity tones produced? By a

blow on the cheek or the open mouth the resonance tone of the mouth cavity can be made to sound for an instant; in this way you can make the mouth say the vowels. If these blows could be repeated rapidly enough you would hear the vowel tones added to another tone produced directly by the blows themselves. They cannot be rapidly repeated by the hand, but the puffs from the larynx can be used instead. This is what occurs in actual speech; the larynx emits a series of puffs (heard as the cord tone), each of which strikes a blow on the air of the vocal cavities, and sets it in vibrations corresponding to their sizes and shapes.

This view of the nature of vowels has been definitively established in regard to the male voice in the chest register for German by Professor Hermann, and for English by my results. For the female voice and for the head register the matter has not yet been settled.

This view is directly contrary to the Helmholtz theory, according to which the cords give out vibrations of a complex character, and the vocal cavities reinforce some of the overtones. As the Helmholtz theory is largely used for the basis of instruction in vocal music, the need of a revision of methods is apparent.

Not long ago I stated these facts to a well-known clef club, and supported them by the curves of German vowels sung into and traced from a phonograph by Professor Hermann of Königsberg; by pictures of spoken English vowels obtained in a different way by Professors Nichols and Merritt of Cornell; by analyses of Finnish vowels by Dr. Pipping of Helsingfors; by direct observations of the vocal cords made by Dr. Musehold according to a new method, and by the results of other investigations. The statements were received with a dismay, mitigated only by incredulity. One member even remarked that such views "would, if true, knock all our theories of vocal instruction into a cocked hat." There was, in fact, a natural reluctance to giving up the Helmholtz overtone-theory of vocal resonance. The abandonment of the incorrect theory of vocal action will probably require modifications in the present methods of vocal instruction, but that is a matter for the musicians to decide. I merely suggest that if the mouth-resonance cannot alter the sound from the cords except by mixture of new tones with it, it is hopeless to attempt to correct faulty cord-action by adjustment of the mouth; the cords must be trained to emit such forms of explosions as will produce the best effects on the ear.

The voice curves contain much further information. The curve of "So," for example, shows that alternate groups of vibrations are of diminished intensity; this would be expected to indicate some sort of a low rumble an octave below the tone of the cords, and it is, in fact, just what is heard when the disk is made to speak. It is exactly the rumble that occurs regularly in a voice when a particle of liquid has lodged in the throat; we have thus a record of the drink in its effect on the voice in this particular "Toast." As one of my flippant students once remarked, such records are a "good way of getting onto a man's curves."

Still another field of strange interest lies before us, but it is yet utterly unexplored. We can all detect sorrow, anger, fear, fatigue, etc., in a person's voice. Since the voice travels in the form of air-vibrations from the speaker's mouth to the ear, a record of these vibrations must contain the results of emotions. An understanding of the modifications of the speech curves must reveal the effects due to the emotions: it is only a matter of skilful recording, measuring, and analyzing to detect them.

My second method of studying curves consists in tracing off the curves of a celluloid phonograph cylinder made in Paris. As this phonograph speaks only French, the results are mainly of interest to students of language, but for French they open up an entirely unexplored field. No good curves of the French sounds have ever been obtained. The machine was built by a special appropriation from the Elizabeth Thompson Science Fund, and is now at work on cylinders of French speech specially made for the purpose.

DOCTRINE OF SURVIVORSHIP IN CASE OF TWO OR MORE DEATHS IN A COMMON DISASTER.*

By THEODORE SUTRO,
OF THE NEW YORK BAR.
PRESIDENT OF THE SOCIETY OF MEDICAL JURISPRUDENCE.

The simultaneous death on August 14 last of a childless young married couple of great wealth, as their forty-five horse-power automobile crashed into a tree while speeding at the mad rate of at least sixty-two miles per hour, on the road from Trouville to Paris, France, gave rise to a good deal of controversy in the public press and at gatherings of physicians and lawyers about the presumption of survivorship, as bearing upon the disposition of their estates. As usual, when a scientific question of some difficulty comes up for public discussion, many incorrect notions and crude conceptions of the law bearing on this subject were promulgated, with the dogmatic assurance characteristic of superficial knowledge. I therefore thought that a brief consideration of the principles applicable in such a case, with a cursory review of their history and development, would be of interest, especially as this subject appears never to have been discussed by this society. It has been impossible for me, amid the engrossing cares of my profession, to devote such time to the preparation of this paper as the importance and interesting phases of the matter deserve; my object will be attained if I shall succeed in giving a mere summary of the not inconsiderable mass of material embraced in legislation, decisions, and treatises, and in thereby laying a basis for further consideration and discussion hereafter on the part of other members of the society.

In the case of the Fairs the subject under consideration lost its importance for the reason that wills of the respective parties were discovered, whereby such disposition was made of their estates that the question of survivorship would not have played any great rôle even if a controversy between the respective next of kin of Mr. Charles L. Fair and of Mrs. Fair had ended in a litigation. In view of a compromise,† however, which was effected between the contending parties, a consideration of the result of survivorship in that case would be purely academic, but yet quite interesting, as there has rarely been a case in which death resulted so absolutely at the same instant and practically without any evidence bearing on the question of survivorship. In the account of the case, as nearly as I have been able to gather it from what may *not* be deemed to be the most authentic, and yet the only available source —the public press—it appears that the wife of the gate-keeper of the Chateau Buisson du Mai, in front of which the accident occurred, and the chauffeur

*Read before the Society of Medical Jurisprudence, on January 12, 1903.

†Interest in this matter has been revived since the writing of this paper, by reason of an action commenced by the relatives of Mrs. Fair to set aside the compromise and establish the survivorship of Mrs. Fair.

were the only witnesses. The woman ran to the assistance of the chauffeur, and aided him in extricating Mr. and Mrs. Fair, who, according to one account, were buried beneath the wrecked machine, and, as alleged by the woman, were in the last throes of death. Both had sustained ghastly injuries, and were almost unrecognizable. Mr. Fair's head had been crushed in while his wife's skull was "split," and in so far as these witnesses could state they were both dead, although the woman stated that she saw "the gloved fingers of one hand of Mrs. Fair slowly open, and the foot of Mr. Fair moving as though the leg was drawing up"; but she could not state which movement lasted longer, but on the contrary that they "took place simultaneously."

Dr. Perriquet, who was summoned to the scene after the accident from the neighboring town of Pacy-sur-Eure, stated that when he reached there, about a quarter of an hour after the occurrence, both Mr. and Mrs. Fair were dead. They had apparently been killed outright, and from the nature of the wounds, he was convinced that death was instantaneous in both cases. Questioned about the movements of the body referred to by the wife of the gate-keeper, he said that he was convinced that when these movements occurred life was quite extinct in both.

The chauffeur was too much dazed and frightened to remember anything, but says that when he saw his masters after the accident he believed that both were dead.

It may, therefore, be correctly assumed that if a litigation had arisen about this matter, and the question of survivorship had come up for adjudication, it would have been impossible to ascertain which of the two had died first, and that, in the absence of evidence, any decision in the case would have had to be based upon the fact that their deaths were simultaneous.

Mr. Fair and his wife were not only residents of the State of California, but their property was located there, and it also appears that their wills were executed in accordance with the laws of that State. Had they been residents of a State in which no presumption of survivorship is recognized, the question under examination would not have arisen, even in case of a litigation about their respective estates. But as it happens, California is one of the only two States in the Union in which the doctrine of presumption of survivorship has been almost without change imported from the civil law into the statute law of that State, so that, had the rights of the respective claimants to the estates of the Fairs not been adjusted by compromise, the doctrine of presumption of survivorship would have had to be applied by the Courts, and an opportunity given for a full discussion and adjudication upon the subject.

According to the law of that State on this subject, when several persons perish in the same calamity, and they are over fifteen and less than sixty years of age, and of different sexes (as was the case with Mr. and Mrs. Fair), the *male* is presumed to have survived.

I have not been able to ascertain definitely the contents of the testaments of Mr. and Mrs. Fair, but it appears that each of them willed some or all of their respective estates to the other. It is therefore clear that, in so far as Mr. Fair's testamentary disposition to his wife was concerned, that, under the presumption of his survivorship, and in the absence of *evidence* of her survivorship, would have lapsed; whereas the testamentary disposition of Mrs. Fair's property, in so far as it was in favor of her husband, this would have vested in him. On the other hand, had the wills for any reason been declared invalid, and the respective parties adjudged to have died intestate, the succession to their respective estates would have been governed by the provisions of the California Civil Code (§1386) according to which (Subd. 2) when, as in the case of Mrs. Fair, a person dies leaving a husband and mother, but no issue, one-half of her estate would go to her husband and the remaining half to her mother. On the other hand, in so far as Mr. Fair was concerned, in his case Subdivision 3, §1386 of the Civil Code would be applicable, which provides that when a man dies leaving neither issue, wife, nor parents, but only brothers and sisters, all his estate goes to the latter, who in this case would have been his sisters, Mrs. Herman Oelrichs and Mrs. William K. Vanderbilt, and this, on the presumption of his survivorship, would have included one-half of his wife's estate.

Of course it is idle to speculate upon a purely academic case, and I have only dwelt upon this particular instance so long, as it is of such recent occurrence, and attracted such wide attention, and is so excellent an illustration of the doctrine of survivorship as commonly understood, but erroneously supposed to prevail generally. Assuming the doctrine to have been applied to the Fair case as stated, the question would arise whether this would be the more desirable and more advisable method of the disposition of the property of persons perishing together as they did, or whether the doctrine of the common law is to be preferred, according to which no presumption of survivorship whatsoever arises, but each case must depend entirely upon such evidence as may be adduced by the party claiming title to an estate, with reference to which of the deceased persons lived the longest. In order to arrive at some intelligent conclusion in regard to which of these methods is preferable, it will be necessary to review briefly the principles of the Roman and common law, respectively, governing the subject, in their origin and development. This I propose to do under the following topics:

First: The provisions of the Roman or civil law with reference to the question of survivorship, as originally enacted and still preserved almost intact in various countries, and in two of the United States, and incidentally the presumption of simultaneous death in vogue in some other countries.

Second: The gradual abandonment of all rules of presumption in the jurisprudence of England.

Third: The present state of the law on the subject in the United States.

Fourth: Which of the systems is preferable, the rules of presumption of the civil law, or the presumption of simultaneous death, or the rules of the common law of no presumption whatsoever?

First.—By the Roman or civil law, as laid down in the Digest (Liber 34, title 5, 22, 23), which was published A.D. 533, under a commission from the Emperor Justinian, as a part of the *corpus juris civilis*, and which was the embodiment of the legal wisdom of a thousand years of ancient Rome, republican, imperial and Christian, it was presumed among other things, when a father and son died together in a battle or shipwreck, that the son, if above the age of puberty, outlived the father, but that he died first if under the age of puberty; furthermore, that of persons dying together, if all were over the age of sixty, the youngest, and if all were under the age of fifteen, the oldest, was presumed to have survived. As between males and females

of the same class, the presumption was that the males survived.

I shall not quote the provisions of the Digest *in extenso*, as the same principles substantially were embodied in the Code Napoleon in France, which I shall refer to more fully, and similar rules obtain at present in Italy, Spain, and Greece. On the other hand, in some countries in Europe, as for example, Prussia, Austria, and Holland, the presumption (in the absence of evidence) is that death was simultaneous.

In the United States, only in Louisiana and California, principles almost identical with those laid down in the Code Napoleon, prevail.

The provisions of the Code Napoleon, and of the Code of Louisiana, and the Code of Civil Procedure of California, on this subject, are as follows:

Code Napoleon, Article 720:

"If several persons, respectively called to the succession of each other, perish by one and the same accident, so that it is not possible to ascertain which of them died first, the presumption of survivorship is determined by the circumstances of the event, and in defect of such, by force of age and sex."

The Louisiana Code (Articles 930-931) contains substantially the same provisions as the foregoing. So, likewise, the Code of Civil Procedure of California, Section 1963, Subdivision 41, only that the word "calamity" is substituted for the word "accident" (under which in a certain case in California—Hollister *vs.* Corders, 76 Calif. 649—murder was held to be included under the word calamity).

Article 721 of the Code Napoleon provides as follows:

"If those who perished together were under fifteen years, the eldest shall be presumed to have survived. If they were all above sixty, the youngest shall be presumed to have survived. If some were under fifteen, and others more than sixty, the former shall be presumed to have survived." The Louisiana Code (Article 932) contains the same provisions. So, likewise the California Code (the first, second, and third clauses of Subdivision 41, Section 1963).

Article 722 of the Code Napoleon provides:

"If those who perished together were of the age of fifteen years complete, but less than sixty, the male is always presumed to have survived, where there is equality of age, or if the difference which exists does not exceed one year.

"If they are of the same sex, the presumption of survivorship which gives rise to succession according to the order of nature must be admitted; thus the younger is presumed to have survived the elder."

The Louisiana Code (Article 933) contains the same provisions, and the California Code (Clause four of Subdivision 41, Section 1963) contains like provisions in the following language:

"If both are over fifteen and under sixty, and the sexes are different, the male is presumed to have survived. If the sexes are the same, then the older."

In the last part the California differs from the Code Napoleon, which presumes the younger between those ages to have survived, if both are of the same sex.

The California Code (in the fifth clause of the subdivision of the section referred to) contains the additional provision:

"If one is under fifteen or over sixty, and the other between those ages, the latter is presumed to have survived."

Similar legislation to the foregoing is said to have been advocated by Mr. David Dudley Field, in the State of New York, in his first draft of the proposed Civil Code, which, as is well known, however, failed of adoption.

I have been somewhat specific in giving the provisions of the Roman law, and as subsequently embodied in the Code Napoleon in France, and in other countries, as well as in the States of California and Louisiana, in order to present a clear understanding of what the provisions actually were and still are in the jurisdictions where the principles of the Roman law on this subject prevail at the present time.

Outside of those jurisdictions, however, it may be said that the modern tendency throughout the world, and especially in England and the United States, has been to disregard not only these presumptions of survivorship but all presumptions of survivorship in cases in which two or more deaths occur in a common calamity, catastrophe or disaster.

Second.—This brings me to the second subdivision of my subject. In England the law was for a long time unsettled, and it was so declared judicially by no less an authority than Lord Mansfield, in the year 1767, in the famous case of King *vs.* Hay (1 Sir William Blackstone's Reports, page 640), known as "Lord Mansfield's undecided case." The question of survivorship arose in that case in consequence of the death of General Stanwix, his wife, and his daughter by his first wife, who all died together while crossing the Irish Channel from Dublin, the vessel being lost at sea, and in the quaint language of the report "no account of the manner of her perishing had ever yet arrived." The nearest relative of the General was his nephew, and the nearest relative of the daughter was a brother of the General's first wife, and both applied for administration on the estate. Lord Mansfield declared that there was no legal principle upon which he could decide the matter, and so, on his recommendation, the parties made a compromise.

Thereafter the question was debated in all its phases until the leading case of Underwood *vs.* Wing (19 Beav. 459), which was reviewed in 4 De G. M. & G., 633, and subsequently in the House of Lords in 1860 in 8 House of Lord Cases, 183, which finally settled the law on this question in England, in the enunciation of the principle that the English law was opposed definitely to any presumption of survivorship, and that any claim of survivorship must be proved.

In that case the facts in dispute were with reference to the survivorship of a husband or wife, who died in a shipwreck, the only witness being a seaman, whose testimony was uncertain. Experts were examined as to the comparative duration of life in cases of asphyxia, as between males and females, with the weight of testimony in favor of the survivorship of the male. On the trial in the Court below Sir John Romilly, Master of the Rolls, said:

"It is possible to speculate to an unlimited extent, but to come to a safe conclusion or to a definite result is, in my opinion, totally impossible. . . . My opinion is, that there is no evidence to show me who is the survivor, and the conclusion of law is that I cannot form any decision on the assumption that either was the survivor." And on appeal Lord Chancellor Cranworth said: "We may guess, or imagine, or fancy, but the law of England requires evidence."

The principle laid down in the case of Underwood *vs.* Wing, disregarding the entire doctrine of presumptions of survivorship, has laid the foundation for all subsequent decisions up to the present time, and it may now be accepted as established that

according to the law of England, no presumption of survivorship whatsoever is recognized.

Third.—The doctrine laid down in Underwood *vs.* Wing, of the entire absence of any presumption of survivorship, has been adopted generally in the United States, always, of course, excepting California and Louisiana. There have been numerous decisions to this effect in the various States of the Union.

The leading case in the State of New York is Newell *vs.* Nichols, 12 Hun, 604, being a unanimous affirmance of the decision, and on the opinion below, of Justice Van Vorst, and further affirmed on appeal in 75 N. Y., 78.

In that case a Mr. Charles W. Walter, together with his two children, Joseph and Mary, by his deceased wife, and the latter's mother, a Mrs. Ridgway, were all lost at sea in the wreck of the ill-fated steamship *Schiller*, on its voyage from New York to Europe, in the year 1874.

There was no evidence to show which, if any, of these persons survived the others. The action was brought to obtain a judicial construction of the will of the deceased Mrs. Charles W. Walter, and to determine the respective rights of certain persons mentioned in the will as entitled to remainders depending, as it happened, on the survivorship between the two children.

In the opinion of Judge Van Vorst the authorities are fully reviewed, and the following language used:

"It would seem to be unsafe to rely upon any presumption arising, either from age or sex, in regard to survivorship of persons exposed to a common peril by the sinking of a ship. It is true, that one might, by strength and powers of endurance, survive the other, but the strongest might perish first. Experience in such cases shows that no rule can be unalterably adopted to determine survivorship." . . . "In the case at bar, there being no legal presumption of survivorship, no rights could have been transmitted by one child to the other, nor to his or her heirs or next of kin, and under the authorities above cited, the burthen of establishing a survivorship rests upon the party who claims any portion of the estate through such fact." . . . "It is the merest speculation or conjecture as to whether there was a survivorship at all, and both cannot be entitled. Nor is the necessity of proving a survivorship wholly obviated through an attempted solution of the difficulty by adjudging an intestacy as to the remainder at the death of the children. In such condition the obstacle is not overcome, but only postponed. The legal title was not in the children, and they had nothing, if they perished in the same moment, to transmit."

In the Court of Appeals the question was somewhat re-examined, and Chief Judge Church said among other things, in referring to and concurring in the opinion below:

"The principal points decided are: 1st. That the appellants who claim through a survivorship must prove the survivorship; 2d. That there is no presumption in law of survivorship in the case of persons who perish by a common disaster, as in this case, by shipwreck, without other evidence tending to prove the fact, and hence that the party upon whom the *onus* lies fails to establish it." . . . "It is not claimed that there is any legal presumption that the children died at the same time. Indeed, it may be conceded that it is unlikely that they ceased to breathe at precisely the same instant, and as a physical fact it may perhaps be *inferred* that they did not. But this does not come up to the standard of proof. The rule is that the law will indulge in no presumption on the subject. It will not raise a presumption by balancing probabilities, either that there was a survivor, or who it was. In this respect the common law differs from the civil law. Under the latter, certain rules prevail in respect to age, sex, and physical condition, by which survivorship may be determined, but nothing can be more uncertain or unsatisfactory than this conjectural mode of arriving at a fact, which from its nature must remain uncertain, and often upon the existence of which the title to large amounts of property depends." . . . "There are cases where a strong probability, in theory at least, would arise, that one person survived another, and perhaps as strong as that that there was *a* survivor, and yet the common law wisely refrains from acting upon it in either case. It is regarded as a question of fact to be proved, and evidence merely that two or more persons perished by such a disaster is not deemed sufficient. If there are other circumstances shown tending to prove survivorship, courts will then look at the whole case for the purpose of determining the question; but if only the fact of death by a common disaster appears, they will not undertake to solve it on account of the nature of the question, and its inherent uncertainty. It is not impossible for two persons to die at the same time; and, when exposed to the same peril, under like circumstances, it is not, as a question of probability, very unlikely to happen. At most, the difference can only be a few brief seconds. The scene passes at once beyond the vision of human penetration, and it is as unbecoming as it is idle for judicial tribunals to speculate or guess whether during the momentary life struggle one or the other may not have ceased to gasp first, especially when the transmission of title to property depends upon it, and hence, in the absence of other evidence, the fact is assumed to be unascertainable, and property rights are disposed of as if death occurred at the same time. This is done not because the fact is proved, or that there is any presumption to that effect, but because there is no evidence and no presumption to the contrary. The authorities are uniform upon this doctrine, but the expressions of some of the judges in announcing it are liable to be misunderstood as indicating a presumption of simultaneous death, which is not the rule." . . . "All the common law authorities are substantially the same way, and the rule, which I think is wise and safe, should be regarded as settled."

The most recent decision, and which stamps the authority of the Supreme Court of the United States upon the principle laid down in the leading English and American cases, is the one reported in the newspapers of last Tuesday, January 6, 1903, but the official report of which I have been unable to obtain at this writing, in the Matter of the Rhodes Estate. The facts in this appear to be that Sophia Rhodes of Washington made a will leaving her estate to her son Eugene, and in case she survived him, then to the Young Women's Christian Home of that city. The testatrix and her son were drowned in the wreck of the steamer *Elbe*, January 30, 1895. The personal representatives of the son claimed the estate for his next of kin, on the ground that *prima facie* the title vested in him, and that the burden of proof was upon the Young Women's Christian Home to show that Mrs. Rhodes survived her son. The Supreme Court of the District of Columbia decided that the bequest should go to the Young Women's Christian Home, and the Court of Appeals for the District of Columbia, on the other hand, that the next of kin of the son were entitled. In reversing the last-mentioned decision, Chief Justice Fuller said:

"The rule is that there is no presumption of survivorship in the case of persons who perish by a common disaster, in the absence of proof tending to show the order of dissolution, and that circumstances surrounding the calamity of the character appearing on this record are insufficient to create any presumption on which the courts can act. The question of actual survivorship is regarded as unas-

certainable, and descent and distribution take the same course as if the deaths had been simultaneous."

From the foregoing remark of Chief Justice Fuller it may be surmised, as is in fact true, that notwithstanding the general principle that there is no presumption of survivorship at common law, yet in applying the rules of evidence to the peculiar facts of some cases, certain presumptions are indulged in. For example, when several perish in a common disaster, but in a proved series of successive events, separated from each other in point of time and character, and each likely to produce death, differences of age, sex, health, and the like, may raise an inference of survivorship. Thus in a Florida case (Smith *vs.* Croom, 7 Flor. Rep., 147) in which a father and his two children died together in a shipwreck, and the father was in feeble health and unable to reach the upper deck, which was swept by the waves last, but which the children reached, the father was presumed to have died first.

So, also, the one who was last seen or heard alive, although subject to the same cause of death as those who perished with him, is presumed to have survived the others. Thus in Pell *vs.* Ball (1 Cheves' South Carolina Equity Reports, 99) where a husband and wife perished at sea in consequence of the explosion of a boiler which parted the ship, and the wife was seen and heard calling for her husband after the disaster, but he was not heard to answer, and not seen again subsequent to the explosion, the presumption was that the wife survived the husband.

So, also, in an old English case (Broughton *vs.* Randall, Cro. Eliz., 503) in which father and son were hanged for a crime "in the same cart," and the son moved his legs after the father had become still, the son was presumed to have survived the father.

Fourth.—The foregoing is a brief—a very brief—outline of the original source and present state of the law on this subject. It remains to consider briefly which of the systems indicated is preferable, namely, the rules of presumption of the Roman law, as still in vogue in the Latin and some other countries of Europe, and in California and Louisiana in this country, or the presumption of simultaneous death in all cases as prevalent in countries like Prussia, Austria, and Holland, or the rule of the common law now adopted in England and generally in the United States, of no presumption whatsoever either as to survivorship or simultaneous death.

It must be remembered that in all three systems actual evidence of survivorship overcomes all presumptions, for no legislation has ever gone so far as to hold any of these presumptions to be conclusive. They are in all cases disputable or rebuttable presumptions. The question, therefore, narrows itself down to this: Ought any presumption whatsoever to be indulged in, or ought in every case the determination of succession to depend upon a fair preponderance of credible evidence, as in any other litigated case in which a certain fact is to be proved, and, in the absence of all evidence ought the property of persons thus dying together to be disposed of as if all had died at the same moment of time?

The importance of arriving at some conclusion on this subject is evident from the few cases to which I have already referred as involving the question of title to estates, utterly at variance with what were the probable intentions of the deceased. This importance will appear perhaps still more forcibly in considering, for example, that in case of testator and legatee, the question of survivorship of one or the other, if but for an instant, will determine a lapse of the legacy or the contrary, and the consequent rival claims between the personal representatives of the testator and legatee, and so on, innumerable illustrations might be given of the great difference which the survivorship of one over the other of persons thus dying will make in the devolution of their estates.

In countries where the presumptions of survivorship exist, there have been many learned discussions and disputations among medical and other scientific experts, as to the basis for assuming a continuance of life in male or female, adult or infant, young or old, according to the nature of the calamity in which they met a common death. These discussions have been as various as the disasters in connection with which the presumptions of survivorship arose.

Most of the reported cases have arisen from rival claims to the property of persons who have perished at sea, yet similar questions also have arisen in cases of those who died in a railroad disaster; in a massacre, as, for example, the one at Cawnpore in 1867 (*Re* Wainright, 1 Sev. and Tr., 257) through murder, as in the case of a mistress and housekeeper, when the former had left by will everything to the latter (Doe *vs.* Nepean, 5 B. & C., 32); on the other hand, innumerable are the cases, of course, in which numbers of persons died together, but many of which have not been brought before the courts for judicial determination at all. One of the most frequent is death in conflagrations, in battle, in earthquakes, in explosions; as, for example, on the occasion of numerous deaths from a premature explosion of fireworks in this city on election night last fall at Union Square, and in volcanic eruptions, which will at once call to mind the recent terrific catastrophe at St. Pierre, Martinique, where 30,000 persons were overwhelmed in a common death, with not a living witness to testify as to whether any one of them outlived the others.

The great variety of circumstances, therefore, under which such synchronous deaths may occur, must be considered with reference to the doctrine of presumptions of survivorship. The presumptions in the civil or Roman law are undoubtedly founded on many centuries of observation of usual occurrences "according to the order of nature," as the Code Napoleon terms it, depending on differences of age and sex. All are based on the assumption that the person deemed to have survived, was likely, from superior strength, to have struggled longest against death. And yet we cannot leave out of consideration that comparative health, physical strength, courage, bravery, and self-possession, and in cases of drowning, the ability to swim, the manner of apparel as well as habits of temperance or intemperance, may be as strong factors in assisting or, on the other hand, impeding the struggle against death, as differences of age and sex, and that these fortuitous circumstances may, in a large number of cases, entirely reverse and change the theory of survivorship of the civil law. To these may be added a further element antagonistic to the presumptions of the civil law, that in some cases, according to scientific authorities, the strongest perish first, and the male rather than the female. Dr. Beck relates an incident in which, in a caravan, suffering from want of water in the Nubian desert "the younger slaves bore thirst better than the rest; and while the grown-up boys all died, the children reached Egypt in safety." The same author thinks that persons with a tendency to affections of the head or lungs should be deemed the first victims in cases in which these parts of the body are likely to be affected by the accident or calamity.

Another author claim that death from hunger occurs soonest in the young and robust, their vital organs being accustomed to more pronounced action than those of persons past adult age. (See "Chambers' Pocket Miscellany," Vol. 18, p. 119.) Dr. John J. Reese, in his work on "Medical Jurisprudence," Philadelphia, 1894, says that "in deaths from asphyxia (apnia), as in smothering or breathing noxious gases, as women require less oxygen than men, the probabilities are in favor of the former, other things being equal." He relates that in Paris, in one year, from 1834-1835, there occurred 360 cases of death by inhalation of charcoal vapors, and that of this number, in nineteen cases, in which a man and woman were exposed together, only three survived—all women. Dr. Beck relates a case in which a man, wife, and child were all asphyxiated, while sleeping in a room, from vapors of a coal-stove. In the morning the man was found dead, the child dying, but the woman recovered.

Again, as between young and old, Reese asserts that the very young and very old can stand heat better, but cold less, than persons in adult or middle life.

Dr. Krügelstein relates a case of a young man and his betrothed, who were lost in the Catacombs, near Maestricht, and at the end of the third day they were found, the man dead, while the young woman was resuscitated, and lived to an extreme old age—as an illustration that in cases of starvation, the female has a better chance of survivorship than the male. Böcker claims that women can bear loss of blood longer than men.

In actual decisions under the Code Napoleon some very curious cases have arisen, not strictly based upon differences of age or sex, but rather on additional presumptions which do not appear to have been founded upon any actual evidence. Thus in deciding cases arising out of the massacre of the Huguenots on St. Bartholomew's day, the Parliament of Paris acted on the presumption that the older persons, as having been more likely to have offered resistance, were assassinated first, and in the case of Madame Dumoulin and her two children, it was presumed, probably for the same reason, that the robbers first killed the mother.

In view of these innumerable circumstances, which undoubtedly have a bearing upon the question of survivorship, the presumptions of the civil law, based as they are entirely upon differences of age and sex, and likewise the statutory presumptions in vogue in some countries of simultaneous death, appear neither of them to rest upon any logical foundation. As proof of the futility of all artificial presumptions of survivorship, may be mentioned the case of the loss of the steamer *Asia*, in a storm on Lake Superior, in the month of November, 1882. The captain and mate, who had in their favor strong and hardened constitutions, together with the passengers, including a mere boy and girl, sought refuge in one of the boats. Yet out of this whole number the boy and girl survived, all the rest either sinking from sheer exhaustion, or being drowned as the boat capsized. Again, there are instances recorded in which a woman has survived the whole number of a ship's crew and passengers. Such occurrences as these set at defiance all attempts to formulate any presumption which may be said to have reason or experience in its favor. An arbitrary rule is all that can be arrived at, and taking everything into consideration, the most reasonable and logical rule would seem to be the one which now has been generally adopted in our law, namely, that when it is necessary or important to ascertain or consider which of several persons survived, and there is no evidence respecting the circumstances of the calamity, no presumption whatsoever will be indulged in, but the conclusion adopted that all perished together.

It may well be that on the assumption that, in the absence of evidence, there is no survivorship, the intended testamentary disposition of property made by persons thus dying together, may be wholly nullified and their estates diverted in a manner entirely contrary to what they expected. But this can be readily obviated by inserting a proper clause in their wills, a practice which I have uniformly followed for many years, providing for the disposition of their estate, in case of the occurrence of the death of the testator and legatee or devisee in a common disaster. This is entirely practicable as between husband and wife, and also in most other cases in which it is likely that persons mentioned in a will may perish together, while traveling or otherwise. And on the other hand, in cases of intestacy, it may well be assumed that the statutes of distribution and descent will regulate the devolution of property quite as wisely and well as if complicated and confused through artificial distinctions of survivorship, which cannot be said to be borne out either by uniform experience or to rest on any reasonable or scientific basis.

THE ETIOLOGY AND PREVENTION OF SENILE CATARACT.

By J. WILKINSON JERVEY, M.D.,
GREENVILLE, S. C.

TWENTY years ago a man, then forty years of age, was struck in the right eye by a piece of lime. To-day there is no discoverable trace of injury or disease of the eye, external or internal, save a paralysis of the sphincter pupillæ, which has existed since the injury. The pupil is five to six millimeters in diameter, regular, reacting easily to atropine or homatropine, but unresponsive to eserine. There is no reaction to light or to accommodation, no hippus, and no reflex demonstrable to any stimulation. The anisocoria is very marked, since the pupil of the left eye is normal. Vision in the right eye is 5-100, and in the left 5-70. The vision in the right eye has been thus partially amblyopic ever since the injury. The vision in the left eye is failing. Equatorial radial opacities are faintly manifest in the lens cortex of this uninjured eye; but mark that in the eye with the paralyzed sphincter all the media are as clear as crystal!

There is nothing apparently abnormal in the left eye, external or internal, save the incipient cataract. There is nothing apparently abnormal in the right eye save the paralyzed pupil!

Here then is a case that gives a clue and a clear hint for the partial solution of a problem fruitful of theorizing, but barren of practical results—the etiology of senile cataract, and its treatment without removal of the lens. It seems to be pretty well agreed that nutritional changes are responsible for the development of cataracts of all kinds. Hyperplasia, degeneration—these are results of malnutrition and the essentials of opacification. Undoubtedly nutritional changes are at the very root of many cases of senile cataract, but not in the sense that is commonly supposed. Senility brings nutritional changes throughout all the tissues of the body without exception. These changes are physiological, or may be so regarded. Complete cataract is not present in the majority, but in the minority of individuals of advanced age. It is clear, then, that a change in the pabulum of the lens cannot in many cases be held

as the sole cause of cataract; yet that has been the popular scientific acceptance.

The truth of the matter, and a great and important truth it is, is that nutritional changes, brought about by, or associated with, senility, when they exist in tissues in contact with the lens, irritate and interfere with the physiological activity of the lens, and cause pathological conditions to appear. Certain other factors, in addition to senile changes, may produce this interference, as will be shown.

The theory that nutritional changes in tissues in continuity with the lens tissue influence the character of the lens pabulum and so cause opacification is rather difficult of substantiation, and while it may be true in some instances, the actual proof is lacking. If a theory more plausible is adduced, with a small amount of proof presentable, and the opportunity for further proving ample, should it not receive at least as much consideration as an old theory, plausible only because of the utter hopelessness of theories previously advanced? And especially should it not be considered when, if it can be shown to be probably true, the knowledge would lead to the possibility of arrest of many cases of incipient senile cataract.

The lens is exceedingly sensitive to traumatism or pressure. That is an established fact. It has been shown that repeated tapping on the cornea with an elastic rod will produce lenticular opacities. Arlt, Meyer, Horner, Knies, and many others have placed themselves on record as showing that eclamptic seizures, presumably from various causes, bringing about intense contraction of the intraocular musculature, frequently produce lamellar cataracts. This is not a very rare occurrence. And Stein, cited by Fuchs, has even shown that he could set up opacities in the lenses of young guinea-pigs simply by placing them in the resonator-box of a tuning-fork, which was kept in constant vibration. We may work upon this knowledge with all the better assurance when we reflect that all efforts to prove the development of cataract, as a fixed pathological entity, by the extraction or imbibition of water or abnormal ocular solutions, have terminated unsatisfactorily.

The Significance of Capsulitis.—Much evidence at hand goes to support the views of Schoen that all simple and senile cataracts commence as a "capsulitis." This produces proliferation of epithelial cells sometimes progressing to hyaline degeneration, and perhaps coagulation necrosis. Knies's molecular granulation with swelling fibers is quite compatible with this asseveration. This hypothesis is doubly striking in view of what Forster has shown regarding the effects of slight trituration of the lens capsule with a smooth instrument for the hastening of cataractous development. That such is a fact is easy of demonstration. Weeks, moreover, has shown that this massage of the lens for hastening opacification results in the adhesion of capsule and cortex. This indicates capsulitis with proliferating, or granulation cells, or perhaps exudative matter.

Knies and Treacher Collins, among others, have shown definitely, what most oculists have doubtless seen, that anterior capsular cataract may arise from contact between the capsule and the edges of a perforating corneal ulcer. Cortical cataract is a ready sequent of this condition. Here then, again, we have an evident capsulitis, prefacing opacification. Whether it is of a traumatic or an infective nature is totally immaterial. It is a fact utterly incapable of controversion that conditions ofttimes apparently infinitesimal in importance can produce cataract; this result being often attained by the setting up of a state, which, for want of another term, we must call "capsulitis."

Now, the momentous question arises: Does there often exist in the senile eye any condition, pathological or physiological, which could produce even the minute irritation or traumatism of the lens capsule necessary to the production of opacities in the lens proper? Fraught with significance, the answer is: Yes, there does often exist such an essential condition.

Significant, indeed, is the answer, for with it is born the hope that with this knowledge some, perhaps many, of the human family will be spared the brain-torturing increase of insidious and relentless cataracts, and the harrowing outlook of blindness, to be followed by an operation with a chance of failure.

The Rôle of the Iris.—It is an anatomical fact that a portion of the posterior surface of the iris lies and moves in contact with the surface of the anterior capsule of the lens. In youth, and unless certain changes occur which may accompany senility, the iris is a thin and delicate membrane composed of soft, almost impalpable tissue. The passage of this filmy substance across the surface of the capsule is not harmful. But let the character of its tissues become altered; let them stiffen or roughen, and we have an immediate plausible causation for capsulitis and opacification. For the iris never rests, save while the individual sleeps, and perhaps not even then. There is constant movement, action and reaction, a continual oscillation known physiologically as hippus.

This constant grating of a rough or stiffened iris upon the capsule is, beyond all peradventure of a doubt, one of the great causes of cataract. That it has been overlooked—for I can find no reference to such a thing after reasonably diligent search—is strange; that it should be recognized at once is certain.

It is not a coincidence, we may be sure, that in the majority of cases of cataract it is impossible to obtain full dilatation of the pupil under the influence of mydriatics. It is to be accounted for by the thickening or stiffening of the iridian fibers, and not, as is commonly suggested, by atrophic conditions.

Now as to the causes of these changes in the iris tissue: They are various. There is, first and foremost, preëminent in the causation of senile cataract, arteriosclerosis, which is prone to affect the capillaries, and which may run riot in the distal circulation long before it is discovered; there are rheumatism and gout, with the thickening fibrin or the uric acid in the blood, and the changes they may cause in the vascular system; there are the circulatory changes of Bright's disease and of diabetes, and there are the hyperplasia, the œdema, the rough and sticky exudation, or the inflammatory stiffening that would accompany acute or chronic inflammations of the intraocular structures. Any of these may be the cause of changes which eventuate in cataract. But mark that in these cases the iris, the abnormal, diseased, rough, thickened iris, is the medium by which the cataract is started.

Were the iris not present to bear the weapons of the attacking forces—to rake and scrape and jostle and disorganize the ultra-sensitive lens and its capsule—in many cases no cataract would develop. For, it is to be repeated, it has not been shown that mere interference with the nutrition of the lens by pathological changes in its pabulum can produce opacities; whereas it is often and comprehensively shown that conditions similar to those that have just been described are not only capable of causing, but are prone to cause, cataract.

Let me be understood. I do not propose, for a moment, that all cases of cataract shall be considered

as arising in the manner just outlined. On the contrary, I believe there are certain forms of shrinkage, trauma, and nutritional changes which are quite capable *per se*, of causing the formation of lenticular opacity.

But I am firmly convinced that the vast majority of cases of senile cataract originate and progress in the way described, and doubtless many of the other clinical forms of cataract are brought about in a similar manner.

Cataract May Be Arrested.—At any rate, if this theory of frictional causation by physical interference be correct, or even partially so, it is certain that means can be adopted to prolong, and perhaps to arrest completely the formative process of cataract. For the present, at least, reasoning must necessarily hold the scale over experience, for my work along this line has not yet been of sufficient scope or duration to warrant a professional exposition. But with this friction theory as a working basis the logical and proper procedures are easy of understanding. Förster's hastening process may be valuable in a way, but an arrest or indefinite prolongation of the disease would be essentially practical and invaluable to the majority of the victims of cataract. It has been noted that iridectomy, by some believed to assist in hastening maturity, sometimes seems to prolong the process of formative opacification. In the case related at the beginning of this article it is seen that the lens of the eye in which the iris has been retired from active duty remains clear, while its fellow manifests incipient cataract.

Here then is the glimmer of an immense ophthalmological truth: Interrupt the iris and prevent its activity in those eyes—and they are many—in which iridian friction is irritating the anterior capsule, starting opacification, and the cataractous process will be arrested.

I do not say the opacities already formed will be resolved, and the lens thus become clear once more; yet I cannot persuade myself that this is a physical impossibility, for hyperplastic tissue is certainly sometimes capable of resolution, and degeneration, where there is no actual destruction, may reasonably become regenerate.

How to Control the Iris.—Now, as to the manner of controlling the offending iris: doubtless the ideal method would be to sever the fibers of the motor-oculi, which pass into the lenticular ganglion, and thence innervate the sphincter pupillæ. But this ganglion, reposing near the apex of the orbit, is wholly inaccessible by reasonable means, and to divide its distal fibers as they approach the iris would be a task for Tantalus or Job, were it even physically possible without wholesale destruction.

It might be presumed that the use of mydriatics would serve the purpose, but this would not be wholly satisfactory, since the prolonged use of atropine in sufficiently strong solution to maintain complete paralysis might be dangerous. But here, it may be remarked, is an explanation of the undeniable fact—leaving out of account the temporary advantages of mydriasis in central opacities—that some of the much advertised quack remedies of charlatans do, at times, exert a beneficial and more or less lasting effect upon the progress of lenticular opacities. In younger persons mydriatics would be necessary to restrict the accommodative movements of the lens, but in cases of senile cataract this is obviously superfluous.

These procedures being eliminated, our next and last resource is iridectomy. But, it will be said, iridectomy sometimes hastens opacification. Even so, but, as has been said before, it sometimes prolongs or seemingly arrests the process. Where it hastens the formation of the opacities it is most likely that the lens capsule has been bruised or injured in the course of the operation. Where it exerts no influence, though it has been carefully performed, then the incipient cataract is due to some of the causes not embraced in this theory; but, even then, in either case, no harm has been done save the inconvenience of the slight operation. In those cases the probable causation of which is frictional, as described, it would seem that iridectomy is indicated. But it must be skilfully and delicately performed. No thumb-fingered tyro need attempt it with hope of success, for in care and delicacy and expertness lie the hopes of brilliant achievement here.

Sphincterectomy.—All that is required is a minute nick, a tiny piece snipped out of the pupillary border of the iris, sufficient to break the continuity of the sphincter. This will result in partial dilatation of the pupil, and cessation of hippus.

If the moderate or even continued use of a very weak solution of atropine should seem to assist in the control of the iridian movements and any slight accommodative movements that may be present in spite of age, there is probably no objection to its use.

If, in the course of operation, the iris forceps scrape or rub upon the capsule of the lens, even with the iris tissue intervening, the purpose of the effort may be thwarted, and instead of arrest there may be an increase of progress of the opacities. But, though this should happen, let it be repeated, no great harm is done, and nothing has occurred to endanger the success of the eventual extraction.

I would not be understood as advocating this method to the exclusion of all other efforts. Far from it. Even with this, constitutional treatment is still important. Regular and wholesome diet, consistent hygiene, and all measures, therapeutic and prophylactic, tending to establish the individual economy upon the most wholesome basis are directly indicated. Flushing out the circulation with copious and constant draughts of water, taken at the proper times, I conceive to be a valuable adjuvant in this condition. Glasses should invariably be adjusted to keep pace with any refractive changes that may occur.

It may be superfluous to add that the measures here indicated must be resorted to early—in the very incipiency of the cataractous formation. Where the lens has had a long start on the downward road of degeneration, it will naturally be difficult or impossible to apply the brake with any hope of efficacy.

Of course, the surgeon must exercise the most careful judgment in the selection of proper cases for sphincterectomy—the little operation may be so designated. An illustration will explain clearly. I have now under my care a beautiful case of double zonular cataract in a man thirty-six years of age. For several years he has been a rheumatic sufferer. In the last two months he has had a violent double rheumatic iritis. He now has in each eye three distinct zones of punctate cataract, and, suggestively enough, the equatorial zones are the most affected, while the polar axes and nuclear areas are comparatively clear. It is evident that in such a case it is wiser to allow the pupils to remain normal, since the pupillary spaces are practically free from opacities, and zonular cataracts are proverbially slowly progressive, and often stationary.

Résumé.—To sum up: (1) Many cases of cataract, especially of the senile form, are started and aggravated in their progress by the friction of a ceaselessly moving iris, which has been roughened, hardened, stiffened, thickened, by disease. (2) Many of

these cases can be arrested, or their advance indefinitely postponed or prolonged, chiefly by the careful performance of the simple little operation of sphincterectomy, as described herein.

The Cure of Boils.—A. K. Bond says that the first thing to do is to quarantine the existing boils, so that no more pus may be carried from them by the fingers, or in any other way, to other parts of the feeble skin. To this end antiseptic dressing is necessary. If the core of the boil is loose it should be removed by dressing forceps. Cleansing the wound-hole with peroxide of hydrogen, and dressing with calomel and bismuth will probably secure as quick healing as in any other wound. If the core of the boil is not loose, cut it out with knife and scissors. The core itself is insensitive. Where, however, bacteria foci are bound down by dense fibrous tissue or wherever pus is shut in, the adjacent healthy tissues will be extremely sensitive. The application of pure carbolic acid on an applicator in advance of the knife or scissors will usually anæsthetize the wound sufficiently to permit of thorough work. Peroxide of hydrogen is a great aid to the cleansing, but takes much time. Suppuration will not cease till all infected tissues have been removed. As pure carbolic acid favors suppuration, the last traces of necrotic fibrous tissues in the depths of a deep excavation may better be removed by dressings of pure alcohol. It gives severe pain on the first touches to the wound, but then anæsthetizes the parts it has touched. Fibrous sloughs seem to clear away under it more quickly than under carbolic acid A plug of gauze soaked in alcohol may be left in the wound. The top dressing should be of cotton, to keep the sick tissues at even warmth, and slight pressure to support the tissues is helpful.—*Louisville Monthly Journal of Medicine and Surgery.*

Treatment of Tropical Dysentery.—Frederick Goldsmith insists upon absolute rest to the body and to the intestinal canal. The diet should be left off altogether for a time, or be wholly fluid and as little as possible. Although the patient may be almost continuously on the stool, that which is passed is not fecal matter at all, but merely the product of the highly inflamed bowel. The fæces tend to be locked up behind the diseased part, and to be retained there by the muscular spasm of the affected portion of the bowel, the lumen of which is still further diminished by the œdema present in the mucus and sub-mucus coats. To ensure the passage of the fæces it is necessary to render them as liquid as possible, and for this the sulphates of magnesia or soda are very suitable. The author usually gives one-drachm doses every two hours, combined with a little tincture of opium, tincture of orange and chloroform water, till the motions become feculent, and then every four hours afterward for a few days. To render the deceased bowel aseptic as far as possible, and to destroy the disease-producing germ, injections per rectum are valuable when the disease does not extend backward beyond the descending colon. Methylene blue nine grains, and boracic acid solution two pints, gives the most satisfactory results. The enema should be injected slowly, and if there be still any expulsive effort, the buttocks (which are raised on a pillow) should be pressed together till the spasm passes.—*The Australasian Medical Gazette.*

Portal Anastomosis.—Daniel H. Craig reports the case of a woman suffering from cirrhosis of the liver. Operation was decided on and performed. At the lower extremity of the wound the parietal peritoneum was separated for about two inches in all directions, and the lower extremity of the omentum, after having been for some time exposed to the air and rubbed with a dry gauze sponge, was tucked down into the sulcus formed by thus separating the peritoneum. Six sutures of catgut were used to secure the end of the omentum within this pocket, to the abdominal parietes. Peritoneum closed above and about the omentum with interrupted catgut sutures, and the abdomen closed in three layers, fascia, fat, and skin Relief of symptoms was absolute, and two months after operation the patient declared herself to be so well that she protested against further dieting, medicine or observation. By the above described technique the author avoided multiple adhesions between various organs and the parieties. As the operation does not cure the cirrhosis, though it does dispose of its distressing symptoms, the contraction of the liver may continue, and if it does so any adhesions formed may be put on such tension as to be extremely annoying. Moreover, the author made the incision in the lower half of the abdomen instead of the upper half, and thus preserved the physiological function of the omentum; namely, to protect the intestines from violence and chill.—*Annals of Gynecology and Pediatry.*

On Chronic States of the Circulation Simulating Heart and Kidney Disease.—Graham Steell calls attention to a condition in which the patients have the ordinary symptoms of cardiac failure, shortness of breath on exertion, dropsy and venous engorgement of the liver. On physical examination of the heart there is no evidence of disease to explain the symptoms—at most, some strengthening of the aortic second sound or reduplication, or lack of tone of the first sound in the mitral area with, perhaps, an apex beat somewhat suggestive of an hypertrophied left ventricle. The heart under consideration would be an overstrong one for the average healthy individual, but for our patient it is weak relatively to the burden it has to bear The departure from health is not "weakening of the heart," but increased arterial tension. Pathological derangements of metabolism, and so forth, have increased the peripheral resistance in the circulation to a degree that imples a burden upon the heart, to cope with which implies an unceasing struggle to an even vigorous organ The condition is met with chiefly in women about the time of the climacteric. Treatment should consist largely in regulation of the diet, avoiding starches and sugars and subsisting chiefly on flesh foods and green vegetables. —*The Medical Chronicle.*

The Typhoid Form of Malaria.—A. Billet states that in Algeria there exists a frequently seen variety of malaria which might easily be confounded with the typhoid group of diseases. It is malaria of a typhoid form. The differential diagnosis consists: (1) In the periodicity of the remissions and paroxysms of the fever to be ascertained by the hourly study of the temperature chart. (2) The constant presence of Laveran's hæmatozoon. (3) Mononuclear hyperleucocytosis, with predominence of the large mononucleated cells filled with melanotic pigment. (4) Other secondary points, such as the absence of rose spots, and a negative result with the Widal reaction. (5) Finally specific treatment with the salts of quinine, which nearly always causes a cessation of the infectious symptoms. If it fails to do this, at least it induces true intermittency, and thus settles the diagnosis.—*Revue de Médecine.*

Relapsing Septicæmia.—W. J. Lockard reports a case which was positively one of relapsing septicæmia, recurring after a convalescent period of nine days. The original seat of infection remained unaffected throughout the relapse. Involvement of all the glandular structures showed the relapse to be general with subsequent local foci of infection. Malaria might have been supposed to be a factor, but no malarial organism was found; quinine had no effect, and malaria is unknown on the Western Slope of Colorado. The usual antipyretics were powerless to reduce the temperature. Thermol, ten to fifteen grains, invariably reduced the temperature, even when at its highest, to normal or nearly so, producing free perspiration and sound natural sleep. The antistreptococcic serum was of so great a value in combating the disease and holding it in abeyance, that the author is convinced that had it been used earlier in the disease a fatal issue might have been avoided.—*The Colorado Medical Journal.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

PUERPERAL INSANITY.

AT a meeting of the Obstetrical Society of London, held on January 7, the subject for discussion was puerperal insanity. The majority of those present were well-known English alienists, so that the matter was considered more particularly from the standpoint of the insane expert. The views expressed as to the etiology of puerperal insanity were somewhat divergent, but, on the whole, the conclusions reached by the different speakers were of great interest.

Dr. Robert Jones opened the discussion and said, in part, that his paper was based upon a personal experience of 259 cases, divided into 120 cases during the actual puerperal period, eighty-three during lactation, and fifty-six during pregnancy. Insanity was stated to occur once in every 700 confinements. Insanity was stated to be a characteristic form after confinement, amounting to an almost nosological entity, but this was not the case during pregnancy, nor during lactation, there being no definite type of insanity occurring in connection with these two stages. The divisions were, however, more convenient than typical. The following propositions were advanced by the author: (1) The insanity of pregnancy is more common in first confinements among single women, the disappointment, shame, and disgrace of illegitimacy being an important factor in the mental breakdown. (2) During pregnancy the mental condition is more often acute melancholia than acute mania, and suicidal symptoms, which occurred in 41 per cent., have to be carefully guarded against. (3) The insanity of pregnancy is divided into that occurring during the early months and that occurring during the later months, and in these, the nearer the insanity in point of time to the confinement the more acute are the mental symptoms. Insanity is not more frequent when the sex of the child is male. (4) The insanity of the puerperium comes on after the first confinement in 33 per cent. of the cases, and supervenes suddenly rather than gradually. (5) The cases which occur during lactation present characters of marked general physical exhaustion, and mentally are more often of the depressed than of the maniacal form. Lactation insanity becomes chronic oftener than the insanity of the other periods. There is a tendency to low forms of inflammation, thrombosis, gangrene, and phthisis during the insanity of lactation. Both suicidal and infanticidal promptings are more common in lactational than puerperal cases—that is, in cases in which insanity commenced more than six weeks after confinement. (6) The early symptoms of threatening insanity are loss of sleep and headache, and these should be a forewarning of mental breakdown. The busy delirium of hallucinatory character, ending in acute, restless, purposeless mania with religious and erotic delusions, is characteristic of this variety. [The writer suggested a close analogy between the emotions of love and religion, and agreed with Simpson that the organ diseased gave a type to the insanity, and that in women suffering from affections of the generative organs, the delusions were more likely to be connected with sexual matters.] (7) Etiology.—Heredity is more marked in the direct maternal line in puerperal insanity, is equally paternal and maternal in the insanity of pregnancy. A previous record of hysteria is frequent in puerperal insanity. (8) The pathology is that of heredity and stress. Is the stress due to a toxin? (9) As regards prognosis, cases of insanity during early pregnancy improve toward the end of pregnancy, whereas those of late pregnancy become worse at the puerperium. Puerperal insanity is markedly recoverable; improvement is rapid, being often complete in three months, but generally takes four to five months. (10) Treatment.—All cases presenting headache and sleeplessness must have absolute quiet and rest, and sleep must be procured. Home treatment in all cases, if possible. Guard against unusual and sudden impulses of suicide and infanticide. The presence of the husband aggravates the symptoms. There is much necessity for a liberal and stimulating dietary. Change is necessary in puerperal insanity when cases tend to become stuporous. Menstruation is a sign of mental improvement. Purgatives and iron are well borne.

The questions mainly discussed in connection with the foregoing paper were: If there is such a disease as puerperal insanity, is it due to toxæmia or septicæmia, or both; or is this delirious mania due to extraordinarily emotional disturbances? Does hysteria in youth manifest itself by insanity in later life at the puerperal or other physiological crisis, and should the marriage of neurotic persons be discountenanced?

Dr. Herman thought that the main duty of the physician was to prevent this condition. The chief means of prevention, in his opinion, were to see that the patient got food and sleep. If sleep were absent he thought that the best hypnotic was alcohol, which was much less harmful, if taken too freely, than chloral, bromide, morphine, sulfonal, or other hypnotic.

Dr. Mercier did not think that headache was a common prodroma of puerperal insanity; sleeplessness and loss of appetite he thought were more distinctive features.

With regard to the proposition laid down by Dr. Jones that single women in their first confinement were more subject to puerperal insanity than any others, he thought that if such were the case the condition should be far more frequent in moral countries than in immoral countries. While Clouston says that 75 per cent. of the puerperal cases admitted to Morningside Asylum followed illegitimate births, and 26 per cent. of the cases admitted

to Bethlehem Hospital had had a previous attack of insanity, either one before marriage or one after marriage, which was not puerperal in origin or a previous puerperal attack.

In summing up the opinions expressed at the discussion, it would seem that the conclusions arrived at were that puerperal insanity is due both to septic poisoning and to emotional disturbances. When there is a decided rise and fall in temperature, septicæmia is present. But the evidence is not sufficient to assert that a specific disease actually exists. Hereditary nerve instability, however, plays an important part in the causation of puerperal insanity, while at the same time it would be going too far to discountenance the marriage of women who had suffered from what is somewhat loosely classed under the head of hysteria. Puerperal insanity is—according to the views of most authorities—a condition distinct from that of pure insanity. That septic poisoning is an important factor in its origin appears to be shown by the fact that pure insanity rarely kills, while puerperal insanity is not infrequently fatal to life.

As to the statement of Dr. Jones that home treatment is far preferable for persons in this condition, opinions were divided. Perhaps the majority of physicians are inclined to favor well-managed institutions for patients suffering from puerperal insanity.

METHODS OF CLEANING RAILWAY CARS.

The crusade which is being waged against the insanitary conduct of the street and elevated railways of New York has awakened attention to the question of railway hygiene generally. The American public is inclined to be somewhat too easy-going as regards such matters, and so long as the cars travel quickly and are equipped in a fairly comfortable manner the sanitary arrangements are not looked into, or disregarded as of no account. The discontent, however, so recently and so widely manifested by the inhabitants of greater New York with the service and management of its lines of transportation, has opened up the whole subject of the sanitation and ventilation of railway cars. In view of this attitude on the part of the population of the country, the Medical Record has thought that it would be opportune to make inquiries as to the exact condition of affairs with regard to the methods in vogue of cleaning-car equipment, and of ensuring good hygienic conditions whilst travelling by train. Accordingly, the Pullman Company was communicated with, and the following description was given by its superintendent of the measures taken for the protection of the health of its patrons:

(1) All the cars are thoroughly cleaned at the end of each trip. The upholstery, carpets, and bedding are taken out of the car and the dust is removed from the plush and carpets by means of compressed air; the mattresses and pillows are beaten and aired and the blankets are shaken and aired. (2) The hoppers are flushed automatically each time they are used, and as a part of the process of cleaning given to cars at each end of every trip, the closets and all fixtures therein are thoroughly washed and disinfectant applied. (3) If an invalid occupies a berth in one of our cars, the bedding is removed and disinfected as soon as possible after the berth has been vacated. In the event of an invalid suffering from a known infectious or contagious disease occupying a car, it is thoroughly fumigated under the direction of a local health officer, and the car is not allowed to return to service until proper permit has been issued by such officer. Cuspidors are also frequently cleaned and disinfected while cars are *en route*.

For the protection of the traveling public from the danger of infection from consumptives travelling in cars, the following instructions have been in force for more than four years:

"It is therefore important that the Pullman Company should do everything in its power to prevent the spread of the disease, and to that end it is deemed best that all cars which have been occupied by a consumptive shall be fumigated after such occupancy, and before the car is permitted to make a return trip to its starting point. All cars running to points within regions regarded by consumptive persons as favorable health resorts should be closely watched and cared for, and the car service men instructed to report to the District Superintendent at the termination of the trip if any person suffering from consumption or other contagious or infectious disease has occupied a berth in their cars, and if so measures must be taken by the District Superintendent to have such car or cars immediately fumigated according to the approved methods now in use by the company. In addition to the foregoing, and in order to prevent, as far as possible, the spread of contagion, all cars in such line should be fumigated at least once a month. The spittoons in all cars occupied by sick persons are to be frequently cleaned."

From a consideration of these rules the fact will be gathered that the Pullman Company's regulations as to cleaning and disinfecting are sufficiently comprehensive and should be effective. It goes without saying that this is a matter of vital importance that every precaution should be taken to avoid spreading disease, and to render railway traveling prejudicial to health in the slightest possible degree. When a large number of people are cooped together in a comparatively limited space for a considerable period of time—as is the case during a long railway journey—the opportunities of contracting the disease are greatly increased, and it is therefore essential that extreme care should be exercised to avoid such eventualities. It is probable that, on the whole, there is less fear of disease being communicated on long journeys than whilst traveling in New York under the conditions prevailing on the elevated and street railway systems at the present time. The overcrowding which is so prominent and disgustingly unhealthy a feature of the New York local lines, is absent on the main railways. Long distance railway traveling is far superior in the United States as regards comfort and attention to sanitation than in any country, and although the acme has not yet been reached, such improvements are introduced every year as to convince the public that railway officials appreciate the fact that it is to their best interests to consider travelers in every way.

Manhattan State Hospital (West).—Dr. R. C Kemp has been appointed consulting physician to this institution.

The Proposed New Jersey Sanatorium for Tuberculous Diseases.

The first annual report of the Board of Managers of the New Jersey Sanatorium for Tuberculous Diseases has just been published. In the first instance, the Board of Managers has made an approximate estimate of the number of persons suffering from tuberculosis in New Jersey who are in indigent circumstances, and who are suitable subjects for sanatorium treatment. It was found that a building with a capacity of 250 patients would meet the necessities of the case. As to the cost of erecting such a hospital, and of furnishing it with all the appliances needful in the treatment of these patients, it was decided that a sum of at least $300,000 would be necessary. The last Legislature of New Jersey appropriated $50,000 for this purpose, a part of which the Board of Managers has expended in purchasing a site, and have furthermore retained an architect to draw plans for the construction of plain, substantial, two-story pavilions for the accommodation of 125 men, and the same number of women, if possible, in single rooms, and for the erection of separate buildings for the administration, dining-rooms, recreation-rooms, kitchen, laundry, power-house, and rest-cure shelters.

The report points out that there can be no doubt that the establishment of a sanatorium for this class of people is an economic measure, as well as a philanthropic one, since through its agency many will be restored to good health, and thereby placed in a condition to support themselves and those dependent upon them, while without such treatment they would become a burden to the community, and an increasing source of infection at no distant date.

The following amendments to the law establishing this sanatorium are also recommended by the Board of Managers to empower it: (1) To restrict admission to curable cases of tuberculous diseases of the respiratory organs. (2) To designate the physician or physicians, upon whose certificate only, application shall be made to the Court of Common Pleas, as provided in Section No. 9 of the Act, and whose certificate shall be taken as a *prima facie* evidence of the existence of pulmonary tuberculosis in the curable stage.

The views of the Medical Record with regard to the *care* of indigent consumptives has been so frequently stated of late that it would be superfluous to dwell further on the subject. Suffice it to say that the report of the managers of the New Jersey Sanatorium for Consumptives seems quite reasonable. The Legislature of New Jersey will be acting wisely if it grants the sum required without demur, on both humane and economic grounds.

Electrotherapeutics and Quackery.

At the first annual meeting of the British Electrotherapeutic Society, Mr. Edmund Owen delivered an address in which he deplored the lack of proper recognition of the treatment of diseases by electricity, on the part of the medical profession, and attributed to that cause the fact that the medical use of electricity had fallen largely into the hands of quacks. While we cannot agree with Mr. Owen as to cause and effect, our inclination being rather to reverse the order, we heartily concur with him in that the practice of electrical therapeutics is largely in the control of those whose consciences are somewhat blunted and those whose enthusiasm conjures up at times strange dreams. The fact that there are scarcely a handful of reputable authorities in the world to-day who have any faith in or knowledge of the therapeutics of the static form of electrical manifestation, and that there are hordes of users of this method whose voicings betray their ignorance of even the elements of electrophysics, is significant at least. Turning to so-called galvanic electricity, which has been somewhat explored by able and reputable scholars and put upon a comprehensible basis, we find one recent writer speaking of "a boil that a surgeon had opened, and then the germs got in and the trouble began." He "placed a needle in the boil and turned on about two and one-half milliamperes of *negative electricity*," and the cure was speedy, etc., while others are reporting cures of every ailment from chilblains to cancer, and reporting the same with the most ingenuous disregard for the accepted theories of electricity.

The wide-spread employment of the Röntgen ray will do more to bring about a dissemination, if not a deeply grounded knowledge, of apparatus and electric manifestation and effect upon the human system than anything that has occurred for many years.

Treatment of Graves' Disease with the Milk of Thyroidectomized Animals.

Ballet, Enriques, Mobius, and Lanz have had some success in the treatment of patients suffering from Graves' disease, by feeding them exclusively on goat's milk, from animals in which the thyroids had been removed. Their theory was that these animals would in all probability develop in their organisms a substance which would neutralize or otherwise fix the toxin in these patients. The results were very encouraging. More recently Goebel treated a patient in the same way with good results, but his theory is unique and may lead to further developments. He suggests that patients suffering from a hypersecretion of thyroidin, could be greatly benefited by excluding iodin from the food, as that in the thyroidin is probably directly derived from the food. The best and safest way to obtain such food appeared to him to get the milk of an animal which, on account of having been thyroidectomized could not secrete any iodin. It is suggested to feed the patient on such milk exclusively.

Human and Bovine Tuberculosis.

There is still a great difference of opinion as to the identicalness of human and bovine tuberculosis, although the majority of investigations undertaken to determine the point somewhat tend to disprove Koch's theory. In the *British Medical Journal*, January 31, is an article by Dr. Nathan Raw in which he puts forward the suggestion that bovine and human tuberculosis are distinct forms of the disease, but that bovine tuberculosis can be contracted by human beings and especially by children. With regard to the disease called tabes mesenterica, which is classed as tuberculosis, Dr. Raw says that we must ask ourselves the questions, "How does the bacillus gain entrance to the mesenteric glands?" and "why is the disease not decreasing with other forms of tuberculosis?"

Dr. Raw then goes on to say: "From a recent case, I made cultivations of the mesenteric gland on blood serum with glycerin, and to my surprise the growth exactly corresponded to bovine tuberculosis or perlsucht." Again he says, "From a case of strumous knee-joint, I made a cultivation of the lymph from the interior of the joint with an exactly similar result. The cultivations which I have previously obtained from phthisical sputum have generally shown the usual characteristics of human tuberculosis, and never bovine. From these two

cases, together with a general survey of clinical facts, I feel there is some reason to suppose that whilst bovine and human tuberculosis are distinct and separate diseases, yet the human subject is susceptible to bovine tuberculosis, and that bovine tuberculosis may set up serious lesions in the human body.

Dr. Raw draws the following conclusions: (1) That there are two distinct varieties of tuberculosis affecting the human body, one produced by human tuberculosis, and the other by bovine tuberculosis. (2) That human and bovine tuberculosis are separate and distinct. (3) That bovine tuberculosis entering the alimentary canal in milk may set up tabes mesenterica, more especially in children. (4) That bovine tuberculosis is probably the cause of enlarged lymph glands, tuberculous joints and lupus. (5) That true human tuberculosis, or phthisis pulmonalis is always conveyed from one person to another by infection, and generally from advanced cases of phthisis. (6) That every effort should be made to stamp out tuberculosis in cattle, and that milk should be boiled before being given to children.

Vaccination in Great Britain.

An influential deputation of the recently-formed Imperial Vaccination League—including prominent medical men and laymen—waited a short time ago on the President of the Local Government Board, in order to represent to him the necessity for introducing a Vaccination Bill in the next session of Parliament, and in particular to urge the desirability of instituting a system of compulsory vaccination in Great Britain. Among those who spoke was Dr. J. C. McVail, a recognized authority on the subject in England. He dwelt on the importance of obligatory vaccination of children before leaving school, and declared that the present vaccination acts referring to children were simply half-measures. There was, he said, "no evidence in favor of primary vaccination of infants which did not equally apply to the revaccination of adolescents. . . . The essential points of the request made by the Imperial Vaccination League with regard to revaccination was that, when a child was approaching twelve years of age, the duty should be impressed on the parent of seeing that that child was protected against smallpox before entering on its further career. If early revaccination was adopted in England, as in Germany, epidemics of smallpox would disappear or be minimized. There would be great economy in the provision of smallpox hospital accommodation, and there would be an enormous saving in the supply of glycerinated calf lymph, as the demand would be more regular.

Prof. Clifford Allbut, referring to lymph, said "the enforcement of revaccinat on rendered greater the obligation upon the Local Government Board to see that the lymph used was beyond even suspicion. At present the private practitioner was compelled to have recourse to private firms, and only three or four of these gave any adequate public guarantees of the efficiency of their processes and the purity of the product which they sold."

The points mainly touched upon in discussion were the great importance of revaccination and the necessity of being able to procure lymph guaranteed pure. Revaccination is absolutely essential to prevent the spread of smallpox, and how well it acts, when carried out in a thorough manner, has been clearly shown in Germany. Revaccination is neglected in many parts of the United States, and to this fact may probably be attributed the prevalence of smallpox during the past three years. The question of pure lymph is another serious one. The Medical Record has always recommended that the process of producing lymph should be strictly supervized by Government or State, so that the medical practitioner may be able to depend upon getting a genuine article. There would seem to be, however, no need to place the production of lymph in the hands of Government; so long as the private manufacturers are kept under strict supervision, enough will have been done. Efficient revaccination and a guaranteed pure lymph will in the course of a few years, stamp out smallpox.

Tuberculous Peritonitis.

Dr. G. A. Sutherland of London has come to the following conclusions regarding this disease: (1) In uncomplicated tuberculous peritonitis the prognosis is good. (2) When tuberculous pleurisy is present the prognosis is still more favorable. (3) The prognosis is rendered less favorable in the case of (*a*) a strong family history of tuberculosis; (*b*) an infancy passed under bad hygienic and dietetic conditions; (*c*) a constitution of feeble resistant power; and (*d*) a history of severe life. (4) The prognosis infective illness in early is rendered less favorable in the presence of one or more of the following symptoms: Continuous pyrexia, rapid wasting, persistent diarrhœa, rapid pulse, and recurrent acute exacerbations. (5) The prognosis is rendered less favorable in the presence of one or more of the following local complications: (*a*) Tuberculous ulceration of the bowel; (*b*) extensive caseation of mesenteric glands or of tuberculous masses; (*c*) localized suppuration from infection through glands or the intestine; and (*d*) obstructive symptoms from bands or matting of the intestine. (6) The prognosis is bad in the case of the following complications: (*a*) Rupture of a suppurating gland or the perforation of an intestinal ulcer into the peritoneal cavity; (*b*) pulmonary tuberculosis; (*c*) tuberculous meningitis; and (*d*) general miliary tuberculosis. (7) In tuberculous peritonitis the prognosis is not appreciably affected by laparotomy.

As to the treatment of tuberculous peritonitis, since the adoption of surgical measures, many think that such a procedure is the sole means of cure. Nevertheless, somewhat of a change has recently taken place in the attitude of physicians and some surgeons with regard to surgical interference, Dr. Guthrie thinks that the treatment should be mainly symptomatic, with rest in bed, and, after recovery, hygienic. While Mr. Watson Cheyne is of the opinion that laparotomy is of much value in certain cases of tuberculous peritonitis, and while admitting that it is difficult to understand how laparotomy can be beneficial, thinks that the reason may be that it possibly alters the tension of the circulation, and thus gives indirectly a stimulus to reparative changes.

It is certain, however, that laparotomy does not find the favor it did but a comparatively short time ago for relief of tuberculous peritonitis.

Anti-Football Legislation.—A bill has been introduced into the Illinois Legislature placing a ban on football, and providing for a fine of from $10 to $100 for any player, or any college, or school officer who "permits, encourages, or allows students under his control to participate in the game."

News of the Week.

A Venerable and Venerated Contemporary.—The first issue of the *Boston Medical and Surgical Journal* as a weekly journal under that title appeared February 19, 1828, and with its issue of February 19, 1903, it therefore celebrated its seventy-fifth birthday. The *American Journal of the Medical Sciences* was established as a quarterly publication in Philadelphia in November, 1817, and *The Lancet* appeared as a weekly journal in London on October 5, 1823. In the first editorial announcement in its issue of seventy-five years ago it was said: "Whether it will be continued in its present form will be determined by experiment. As it is devoted to no party or institution, the editors (and Board of Management) offer it to the medical profession as a vehicle for such publications as they may wish to make; and they hope by it to bring out the talent of this part of the country." Time has determined this, and to-day, as throughout its past, our valued contemporary pursues its upright and conservative way, bringing out the talent of its part of the country, serving as a vehicle for the publications of the physicians of New England, and upholding the honor and dignity of the medical profession throughout the world. With our hearty congratulations go our wishes for longer life and continued prosperity.

The Rockefeller Institute for Medical Research.—As was previously announced in these columns, the scope of this institute has recently been greatly enlarged. As originally established, the institute had no home of its own, but the funds were employed in the form of scholarships, in furtherance of investigations carried on by some twenty workers in the universities of Columbia, Harvard, Yale, Johns Hopkins, Pennsylvania, Chicago, Michigan, McGill, Wesleyan, California and the Western Reserve, in this country; in Ehrlich's laboratory in Frankfort, and in the Institute for Infectious Diseases in Berlin. Besides extensive observations relating to the milk supply of New York City and its effect upon the health of children, other subjects investigated have related to tuberculosis, tetanus, typhoid fever, dysentry, diabetes, immunity, vaccina and smallpox, and the relation of mosquitos to disease. It has now been decided to concentrate the work in a special way, and to establish in this city an institute of medical research which will be without equal in this country, and unsurpassed in any city in the world. Dr. L. Emmett Holt, secretary of the board of directors, has prepared a statement of the plans of this project so far as they have been determined upon. In June last, he says, Mr. Rockefeller gave to the institute the additional sum of $1,000,000 for the purchase of a site and the erection of a laboratory in which to begin the work of the organization of the institute along broader lines. After due consideration of the advantages offered in other cities, New York was unanimously selected as possessing greater advantages than could be obtained elsewhere in America. The directors have secured Dr. Simon Flexner, professor of pathology at the University of Pennsylvania, to take charge of the new work, beginning with July next. The immediate plans of the directors are the erection of a single laboratory building so arranged as to permit of such extension as the growth of the work may necessitate. In this building will be provided equipment for investigations in the following departments: Physiological chemistry, hygiene and preventive medicine, pharmacology and therapeutics, normal and pathological physiology and the study of microorganisms. In order to ally the research work of the institute closely with practical medicine, it is the purpose of the directors to erect in the near future a hospital where special groups of patients may be treated. It is expected that the first laboratory will be ready for work by October, 1904. The institute will also assume the publication of the *Journal of Experimental Medicine*, established some time ago by Dr. William H. Welch of the Johns Hopkins University. It is the conviction of the directors that such an institute of research might wisely have as its aims not only increasing knowledge of the cause and cure of disease, but the education of the people in matters of hygiene. This it is hoped may be promoted eventually by means of popular lectures, a hygienic museum, the diffusion of suitable literature, etc. The following are the directors of the institute: Drs. William H. Welch of Baltimore, T. Mitchell Prudden of New York, Simon Flexner of Philadelphia, Theobald Smith of Boston, and C. A. Herter, Hermann M. Biggs, and L. Emmett Holt of New York.

The Health Officer of the Port of New York.—Governor Odell has sent to the State Senate the renomination of Dr. Alvah H. Doty as Health Officer of the Port of New York. The term of office is four years. Dr. Doty has held this office for eight years, having been appointed by Gov. Levi P. Morton in January, 1895.

Röntgen-ray Treatment of Hodgkin's Disease.—A case of pseudoleukæmia is reported from the University of Colorado Hospital in Denver in which a very notable improvement has followed treatment for two months by the *x*-rays. The patient has gained in weight and strength and the glandular swellings have been markedly reduced in size.

Typhoid Fever at Ithaca.—The epidemic at Ithaca continues with little change, but there has been an improvement at Cornell University. A few days ago it was stated in the daily press that the students at Cornell had petitioned the trustees to supply them with pure water, and that the trustees, some of whom were shareholders in the Ithaca Water Company, had refused. This assertion is pronounced by the trustees of the Universtiy to be absolutely false. They say that no member of the board of trustees owns any stock in the Ithaca Water Company. The university itself does not own any stock in that company. The water supply of the university comes from Fall Creek, which is a different source from the water supply of the city. No case of typhoid fever is known to have occurred among those who used exclusively the water supply of the university campus. No person in Sage College, in which more than 200 women students board and lodge, and which is supplied by this water, has had typhoid fever, and no case of typhoid has occurred in the families of the professors living on the campus. The university authorities have made arrangements to enable the students to secure pure water, duly inspected. Artesian water has been placed in all the university buildings, where the students may draw it freely. Furthermore, some time ago the university secured from boarding-house keepers a pledge to use only boiled water for drinking, to wash all uncooked vegetables in boiled water before serving, and to wash and rinse all dishes used for the holding of food or drink in boiled water. On February 21 there were fifty-four patients, most of them with typhoid fever, in the university infirmary, and these were attended by fifty skilled nurses.

Sanitary Regulations for Barbers.—The Jersey City Board of Health has formulated a number of

rules for the guidance of barbers in their relations with their customers. The barber shop must be swept out and dusted every day, and the floors and woodwork must be scrubbed at least once a week. Barbers must keep their finger-nails short and clean, and must wash their hands carefully immediately after waiting on a customer, and before attending to another. All brushes, combs, razors and other utensils must be sterilized in boiling water or a solution of formalin within five minutes after use, and razor strops must not be moistened with the breath or wiped with the hand.

Damages for an Unauthorized Operation.—A Chicago surgeon has been sued for performing an operation without the consent of the patient, and the court has found him guilty and fixed the damages at $3,000. The plaintiff entered the defendant's hospital for treatment, but was subsequently operated on without her consent or the consent of her husband. She was afterward adjudged insane. It was not asserted that the doctor performed the operation in an unskilful manner and no malpractice was charged. "It cannot be reasonably contended that the doctor acted from any malicious motive," the court said, in rendering decision. "The absence of malice does not excuse an unauthorized trespass on the body of the plaintiff."

Substituting and Adulterating Druggists.—A short time ago agents of the New York City Board of Health detected a large number of druggists selling various other and much cheaper drugs when the prescription given them called for phenacetin. The excuse offered by some of the offenders, when charged with the substitution, was that they had bought the drug in good faith of peddlers who had smuggled it, and so were in a position to sell it cheap. The health inspectors have continued their investigations, and now announce that of 215 samples of Jamaica ginger made by as many different druggists, forty were found to have been made with wood alcohol instead of ethylic alcohol.

A Psychopathic Hospital for New York City.—A bill has been introduced into the Legislature, at the instance of the State Commission in Lunacy, providing for a psychopathic hospital in New York City. The hospital would afford a place for detention and expert examination for persons suspected of incipient insanity. The detention ward at Bellevue serves something of the same purpose now. The hospital would be conducted in connection with the existing psychological institution on Ward's Island, and would be located probably on the East River, opposite the Ward's Island institution. The bill appropriates $300,000 for the establishment of the hospital, for which the city is to furnish the site. It would accommodate from 150 to 200 patients.

An International Congress on Tuberculosis at St. Louis.—It is announced that a World's Congress on Tuberculosis will be held in St. Louis on July 18–23, 1904. The work of organization is being carried on as rapidly as possible by the committees appointed by the American Congress on Tuberculosis, which is now a permanent body and is, we understand, incorporated under the laws of Georgia. An advisory committee, composed of the heads of the medical corps of the Army and Navy and of many presidents of health boards and other santiarians in this country and Canada, has been appointed. The secretary of the organization is Dr. George Brown of Atlanta, Ga.

A Serum for Cholera Infantum.—The Health Commissioner of New York City announces that the bacteriologists of the department are preparing a serum for the treatment of cholera infantum, at least for that form of it which is believed to be due to the presence of Shiga's bacillus.

A Laboratory of Criminal Anthropology.—The Senate Judiciary Committee has made a favorable report on the bill to establish a laboratory for the study of the criminal and defective classes, a similar bill having been reported favorably by the House Judiciary Committee. The bill provides for establishing in the Department of Justice a laboratory for the study of abnormal classes, the work to include not only laboratory investigations, but the collection of sociological and pathological data, especially such as may be found in institutions for the criminal, pauper, and defective classes, and general hospitals and schools. The laboratory is to be in charge of a director appointed by the President, who is to make an annual report to the Attorney-General.

The New General Hospital for Manila.—A despatch to *The Sun* reports that Bishop Brent of the Episcopal Church has secured 6,000 signatures to a petition to the Philippine Commission requesting the establishment of a general hospital in Manila. Commissioner Ide has offered personally to subscribe $10,000 for the endowment of free beds in the hospital. It is believed that the example of Commissioner Ide in heading the list will influence rich Filipinos and foreigners to assist in promoting the scheme. It is also thought the Philippine Commission will give some financial aid to the project.

St. Bartholomew's Clinic.—A special clinic has been instituted for the treatment of gastrointestinal diseases in adults and children. Dr. R. C. Kemp has been appointed to take charge, and Dr. John E. Traub is associated with him in the work.

Obituary Notes.—Dr. William Elias B. Davis of Birmingham, Ala., one of the leading gynecological surgeons of the South, was killed on February 24 by being run over by a railway train. He was born in Alabama, near Birmingham, on November 25, 1863, and was graduated from the Bellevue Hospital Medical College, New York, in 1884. He began practice in Birmingham immediately after graduation, and continued to practise there, with the exception of a few months passed in Rome, Ga., up to the day of his death. He was one of the founders of the Southern Surgical and Gynecological Association, and served as its secretary for many years until elected president. He was an ex-president of the Tri-State Medical Society of Alabama, Georgia, and Tennessee, and was also an active and prominent member of the American Medical Association.

Capt. Franklin M. Kemp, Passed-Assistant Surgeon, U.S.A., died at Nueva Caceres, Philippine Islands, on February 23. He was born in Holbrook, Suffolk County, N. Y., and was appointed to the medical corps of the Army in 1896. In 1898 he served with the exploring expedition in Alaska under Captain Eldridge and went to the Philippines in 1899. Returning to the United States the same year, he was assigned to duty at West Point, where he remained until November, 1900, when he went back to the Philippines.

Dr. Wilbur A. Blauvelt died at Newark, N. J., on February 19, at the age of twenty-seven years. He was a graduate of the New York University Medical School in the class of 1900.

Dr. Ashley A. Webber of Brooklyn died on February 19, at the age of forty years. He was a native of Maine, and was graduated from the New York University Medical School in 1888. He was physician to the Eastern District Hospital and a member of the Kings County Medical Society.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE KING'S HEALTH—SHELL-FISH—GASTRIC AND DUODENAL ULCERS—DISLOCATED HIP—ATAVISM?—MUSICAL MURMURS.

London, February 6, 1903.

Disquieting rumors as to the King's health were flying about at the end of last week. On Monday a projected journey was postponed, as His Majesty had a "feverish cold." On Tuesday it was announced that a mild attack of influenza had developed, and the King was confined to his room, but not to bed. The attack is so mild that formal bulletins have not been issued, but an official statement has been made daily on the authority of Sir Francis Laking that His Majesty is progressing satisfactorily. Sir Francis has continued in attendance, and it has not been considered desirable to call for a consultation with either of the other court physicians.

The County Council, on a report of the Health Committee, has asked the Local Government Board to take steps to obtain power to prohibit, under heavy penalties, the laying down of all edible forms of shell-fish in sewage-polluted creeks or other dangerous localities, and the sale of such shell-fish for human food; also that all unpolluted layings, fattening beds, and storage ponds now in use may be protected from pollution.

Dr. Collingridge, M.O.H. for the city, has prevented a report in which he says Dr. Klein's experiments show that the whole of the Thames estuary is polluted, and the fish, therefore, contaminated or under grave suspicion. All shell-fish, he says, should be examined and, in addition all sprats, whitebait, and smelts, these being eaten "uncleaned," should be subjected to cooking of such a nature as to secure a high temperature throughout the whole fish.

Mr. Moynihan communicated his experience of the surgical treatment of gastric and duodenal ulcers to the last meeting of the Medico-Chirurgical Society. For perforated ulcers he operated on ten cases with four recoveries; for chronic ulcers gastroenterostomy was done on fifty-one cases with one death. Three cases of pyloroplasty were performed with no death. Eight cases were operated on for hemorrhage; in one an ulcer was excised and the patient died on the eighth day; in one an ulcer on the posterior surface was excised and a gastroenterostomy performed, the patient recovering; in six gastroenterostomy alone was performed and all recovered.

Mr. Moynihan laid stress on the following points in connection with gastroenteostomy: (1) Sterilization of mouth, stomach, and jejunum. As soon as a patient is admitted preparation of the mouth is begun, the teeth are cleansed and brushed frequently with Condy's fluid; all food is liquid and sterile; the stomach is washed out twice, once about thirty-six hours before operation and again about six hours before with tepid boiled water. A dose of calomel is given forty-eight hours before the operation. (2) Thin rubber gloves, boiled, are worn by operator, assistants, and nurse. (3) The hands are washed and instruments rinsed in salt-solution; no antiseptic is allowed to touch the peritoneum. (4) Care is taken to avoid possible infection from the mucosa; instruments which touch it are immediately laid aside and not used in subsequent stages. As soon as the suture of the membrane is completed the gut is lightly washed with saline solution and the hands thoroughly cleansed.

Mr. Moynihan considers that operation is required for these ulcers whenever perforation has taken place; when hemorrhage is profuse or recurs frequently; when chronic dyspepsia, due to dilatation, pyloric stenosis, or hour-glass contraction, is distressing. Perforation calls for immediate operation. In duodenal cases the escaped fluid runs down the outer side of the ascending colon and the symptoms resemble appendicitis. The incision has, on this account, been made in a number of recorded cases over the appendix. Perforations of gastric ulcers may be classed as acute when the opening is large and the stomach full, so that the contents escape freely; subacute when the reverse conditions make the leakage less and the symptoms subdued; chronic when adhesions limit the leakage, and the result is local peritonitis and abscess. Hemorrhage may occur in either form; in the acute, operation is not often required, in the chronic it should be the rule.

Other points were brought out in this paper, some of which were referred to in the discussion that followed Thus Mr. D Power had found that when drainage was neglected trouble had ensued from subphrenic abscess. In cases confused with appendicitis free drainage was very beneficial. He had seen much mischief from overfeeding after operation.

The President (Mr. Alfred Willett) remarked on the accuracy of the diagnosis shown in the cases before the meeting. In chronic cases drugs were useless and operation saved the patients from much subsequent trouble. The simplicity of the manipulations in the operations described was doubtless a most important factor in the success.

Mr. English said that of forty consecutive cases at St. George's Hospital, twenty-one recovered. In some the symptoms were slight and in others latency was a feature in the reaction stage.

Dr. Newton Pitt said in some cases of acute ulcer he had seen profound anæmia. He asked if post-mortem evidence showed that a hard chronic ulcer ever healed after gastroenterostomy. He thought chronic ulcers sometimes might be solitary, though usually they were multiple.

Mr. Moynihan, in reply, said that in any doubtful case the abdomen should be opened. He had never failed to find the ulcer. He regarded drainage as of less importance than cleansing the peritoneum. In one case not drained there was a subphrenic abscess. He gave fluids early and freely. He feared cases were lost in the early days from starvation. In acute cases anæmia was transient and less profound than in chronic. In his experience chronic ulcers were never solitary, and he had never found a duodenal ulcer without a gastric one also. He did not mean to use a Murphy's button again. The operator should use the suture he was most accustomed to employ. He had never had the chance of seeing post mortem a healed ulcer, but complete recovery of health followed operations.

Two of our societies had clinical evenings last week, and a number of interesting cases were shown. Among them I may mention some. Mr. Openshaw exhibited three cases of congenital dislocation of the hip; one was a girl of seven years, treated by Lorenz's method; another a girl of eight years, by Hoffa's open method; the third a girl of thirteen years, with both hips dislocated, and who had not been treated. Mr. Openshaw did not regard this case as hopeful. He thought Lorenz's method gave good results up to the age of five years, but after that Hoffa's was better. Mr. Keetley and Mr. Ballance both considered Hoffa's open method generally preferable.

A child of three years was shown by Dr. Poynton as a case of atavism. He could not walk properly. When placed on his feet he stood erect at first, but on trying to walk he "crouched in the attitude of a chimpanzee." The whole body was bent forward, the head bowed, and the chin pointed to the right. The hands were held in front, the wrists and elbows bent, hips and knees flexed, the feet turned in so that the pressure fell on their outer borders. As the child got tired the crouching attitude became more marked. The penultimate phalanges of the fingers and toes were longer than normal and their movements very free. Is that a sufficient reason for suggesting a return to the condition of a "remote ancestor?" Mr. Muirhead Little, Dr. Cautley, and Dr. Voelcker commented on this case.

Two cases with musical murmur were shown, but not at the same society. One in a man of forty-four years. It was loud, diastolic, almost suggestive of a ruptured valve, but there was no other sign of that. No history of syphilis, rheumatism, sudden access of pain, etc. The patient discovered that he had a wheezing in his chest and later got short of breath. There was a thrill. In the other case there was history of syphilis, sudden seizure, marked diastolic thrill, the murmurs distinctly heard two inches off, and with a stethoscope all over thorax, on abdomen down to navel and down the arm, no other sign of aneurysm.

Dr. Morison thought the case aortic regurgitation with loss of compensation; ruptured valve was rare, came on suddenly, was continuous and cumulative. Dr. Cayley agreed with this view and did not consider musical murmur with marked diastolic thrill sufficient for diagnosis of ruptured valve. Dr. Pearson had seen a similar case, which proved at post mortem to be dilated-aortic orifice with failure of compensation. Dr. Taylor, who showed the case, admitted doubt, but regarded the syphilis, the loudness of the murmur, and the patient's occupation (a hammerman) as supporting his view.

A Contribution to the Surgery of the Internal Saphenous Vein.—William Francis Campbell recommends the following procedure in ligating the internal saphenous vein: Find the spine of the pubes. From this point project a line three and one-half inches long at right angles to Poupart's ligament. The end of this line marks the point for the center of the incision, which should be about one inch long, and parallel with the fold of the groin. In retracting the edges of the incision, retract the upper edge so as to ligate as near the saphenous opening as possible.—*Medical News.*

OUR PARIS LETTER.

(From Our Special Correspondent.)

A NOVEL ON SANATORIUMS—COLLARGOL EMPLOYED IN THE PARIS HOSPITALS—CASE OF ARSENICAL CANCER—EXAMINATION FOR THE INTERNATE—DISTRIBUTION OF PRIZES BY THE ACADÉMIE DE MÉDECINE—AUDHONI'S BOOK ON THERAPEUTICS—CHANTEMESSE'S SERUMTHERAPY OF TYPHOID FEVER.

JANUARY 23, 1903.

A NOVEL recently published in France, called "Les Embrasés," has been the subject of medical discussion. The title of this book, which has been written by Corday, means "On Fire," and deals with dramatic incidents that take place in a sanatorium. The author had already written a novel called "Venus, or the Two Risks," in which he showed the dangers incident to venereal indulgence. In this work he accepts the old dogmatic teaching that consumptives are more prone than others to sexual excitation, and describes the results that follow from the promiscuous gathering of patients of both sexes in such an establishment.

Dr. Cabanès, the editor of *La Chronique Médicale*, asked several distinguished medical men to write him their opinion on the subject, and one of the last numbers of this periodical is full of their answers. Professor Graucher's reply showed that he hardly thought it possible that consumption should undermine the constitution in one manner and strengthen it in another. Dr. Letulle, who is a physician of the Boucicaut hospital, where there is a species of sanatorium for tuberculous patients, gave it as his opinion that tuberculous patients of the female sex were affected with jealousy, but he had not noticed that they were more affectionate. Professor Landouzy sent his answer from Greece, and in it he speaks of the importance of the cult shown to the goddesses of love and fecundity, and he then gives it as his opinion that a sanatorium is not the best place to judge this question. There is, perhaps, an appearance of truth in the popular saying, and it is due to the patient wishing to prove to himself that he is still in fairly good health As for what may take place in a sanatorium, the conditions of life must be taken into account.

Collargol is being used in Paris in the different hospitals, and at a recent meeting of the Medical Society of the Hospitals Dr. Netter described the results he had obtained in various diseases. The ointment used is prepared according to Credé's formula, 15 per cent., and the amount used is one, two, or three grams, according to the patient being a child, a youth, or an adult. Netter has tried it in generalized pericarditis, pneumonia, suppurative meningitis, scarlet fever, diphtheria, and typhoid fever. The results were good, and especially noticeable in the case of a young doctor, who was suffering from pyohæmia, and had been obliged to undergo the operation of nephrotomy. The day after the inunction there was noticeable improvement, the appetite coming back very soon. According to Dr. Netter, this drug does not seem to act as an antiseptic, but rather by neutralizing the toxins.

At a recent meeting of the French Society of Dermatology and Syphilography, Dr. Darier presented a patient suffering from what he considered arsenical cancer. The patient, who is forty-seven years old, had already been affected twelve years ago with an eruption of nævi on the face and neck, and warty excrescences. He was seen last spring, and was then found to be suffering from a transformation of the excrescences into epitheliomata. For the space of ten years, from 1886 to 1896, he had twelve drops of Fowler's solution twelve days a month, and seven days a month from 1897 to 1901. This theory of arsenical cancer, which was proposed by Hutchinson in 1887, has been endorsed by a certain number of observations since then.

The written composition which serves as the first part for the examinations of the Internate of the Paris Hospitals, was given to the candidates on the 13th of December. Three questions are generally chosen by the jury, and one of them is drawn by one of the six or seven hundred candidates. The question drawn this year was: Submaxillary gland. Symptoms, diagnosis, and treatment of ulcer of the stomach. The other questions were: Pulmonary artery, without the physiology. Causes, symptoms, and diagnosis of acute pericarditis. Popliteal region. Articular manifestations of blennorrhagia. The annual distribution of prizes of the Academy of Medicine took place on the 23d of December.

Dr. de Lavarenne, who is the editor of *La Presse Médicale*, made some remarks in an article in his paper on the small number of members present—only about 27 out of 110. Out of thirty-eight prizes only twenty-two were given, and the roll-call was less than usual, as it has been decided that the prizes cannot be awarded to several men. There is a prize, called the Prize Audiffred, which consists of an annual income of $4,800, payable for twenty-five years, and which is to be given to the discoverer of a sure cure for consumption; the author's profession or nationality is not to be considered. A sum of $400 taken from this was allotted to Dr. Besauçon and Griffon for their work on the culture of Koch's bacillus on gelosed serum. The Campbell Dupierris prize of $500 was awarded to Castaigne for his work on the use of methylene blue as a means of gauging renal permeability. Dr. Jaboulay, a well-known surgeon of Lyons, was given the Laborie prize of $1,000 for his book entitled "Surgery of the Nerve Centers, the Viscera, and the Limbs. Eblers of Copenhagen was honored with a prize of $300. Testul of Lyons was awarded the Saintour prize of $900 for his "Anatomy." Dr. Magnan, the celebrated alienist, pronounced the panegyric of Baillarger, the great neurologist of the Salpetrière, which closed the proceedings. A new edition of the "Treatise of Therapeutics," by Victor Audhoni, a well-known physician at the Hotel Dieu, shows how fearlessly a physician will sometimes attack the most admirable discoveries. The author passes severe judgment on antidiphtheritic serum, criticises pitilessly antirabic vaccination, and condemns the new organic compounds of arsenic. Dr. Audhoni is a physician of the old school, and writes in a most clear and vigorous style. Balneotherapy in typhoid fever, and the use of the salicylates in rheumatism, are severely dealt with. It must be remembered that there are to be found physicians practising in Paris, and well-known in certain social circles, who doubt the efficacy of vaccination, do not use the antidiphtheritic serum, or countenance nephropexy by suppuration.

Dr. Chantemesse had already published last year, in the *La Presse Médicale*, the results he had obtained in the treatment of typhoid fever by the use of his antitoxic serum. He has again brought before the medical public a new series of cases with the results as regards the mortality. He prefaces his description with the remark that sometimes one may be the victim of a fortunate series of patients, and he, therefore, has examined, at the same time, the statistics of the cases seen in the other hospitals of Paris, and treated cold baths. From April 1, 1901, to December 1, 1902, there were 1,478 cases of typhoid fever treated in eighteen of the large hospitals in Paris, and there were 286 deaths amongst this number, which makes a mortality of 19.3 per cent.; sometimes it was more in some hospitals, sometimes less. For instance, at the Lænnec Hospital there were 44 cases in 1901, without a single death; in 1902, with 42 patients, there were 11 deaths. During the same period of time, from April 1, 1901, to December 20, 1902, there were 186 patients with 7 deaths, which makes a percentage of 3.7 per cent. There was also one death from diphtheria, which is not included in these statistics. Dr. Chantemesse considers that the difference in his statistics due to serumtherapy. The seven deaths were due to the following causes: First case, severe hemorrhage and pneumonia; second case, typhoid fever with syphilis and blennorrhagia; third case, brought to hospital in comatose condition, purulent peritonitis found at autopsy. Fourth case, a young woman with peritoneal pains, symptoms of intestinal obstruction. In three cases death was due to perforation. Two other cases of perforation were operated on and recovered. There were no cases of perforation in patients injected during the first week. If one adds to the 186 patients mentioned above, 70 cases already treated with 4 deaths, and 100 others with 6 deaths, results of former statistics, one finds that the percentage is 4.7 per cent. This treatment was also carried out at Toulon at the marine hospital, 151 sailors being injected, and there being only 13 deaths. These results are certainly better than those obtained in the German army, where there were, last year, 020 cases of typhoid fever with 87 deaths, or an average of 9½ per cent. Dr. Chantemesse has also remarked that local complications of the bones were rapidly ameliorated by the use of the serum.

Congenital Unilateral Paralysis of the Velum Palati.—Deguy has a patient, now a young man, who has always had unilateral paralysis of the velum palati. The left half of the velum is flaccid and immobile, and there are resulting troubles of phonation and deglutition. Nothing suggestive is noted in either the family or personal history. There is no particular history of syphilis. The patient has a good appearance. At the age of one year he had an attack of convulsions, which never recurred and which left no trace. The electrical examination of the velum shows a diminution of electrical contractility of the palatine muscles, and especially of the posterior pillar. The musculature is atrophied in the entire left part of the velum, and especially in the posterior pillar. The diminution of the contractility appears proportional to the degree of muscular atrophy.—*Le Bulletin Médical*, January 24, 1903.

REPORT OF THE CHOLERA EPIDEMIC IN THE PHILIPPINES.

(From Our Special Correspondent.)

MANILA, January 12, 1903.

REPORTS are now being received from medical officers of the army relative to the epidemic of cholera in the Philippines, especially as it has directly or indirectly affected the health of the troops. An exhaustive report by Major C. E. Woodruff, Chief Surgeon of the Third Brigade, Batangas, Luzon, summarizes the reports rendered by the surgeons at twenty-four military stations in Laguna and Batangas Provinces, Luzon, and complies with instructions issued from the office of the Chief Surgeon, as follows:

1. To investigate, as far as possible, the causes of the infection of the Provinces with cholera.

2 To investigate the unduly high proportion of deaths from cholera in the Ninth Cavalry, and Second and Eighth Infantry.

3. To determine how far general orders issued for the government of troops relative to cholera were complied with, and how far any disobedience of these orders could be considered as responsible for the spread of the epidemic.

4. To investigate the state of discipline in the companies most affected.

The report states that the infection was carried into a new field either by infected persons coming from districts in which cholera was prevailing, or by infected moist food. The first method was by far the most common, and in nearly every authentic instance there is direct proof that there was a newcomer who was infected prior to arrival, and was taken sick shortly afterward, often on the same day. The second method was much less frequent, but was shown most clearly at Biñan where a native cook from Manila smuggled infected food through the quarantine guard of Biñan, under the name of coal oil. These foods were served at a native fiesta, to which the first eighty cases of cholera in Biñan were directly traceable. The cook himself died of the disease a few hours after arrival, and was probably infected in Manila from the same source as that from which the foods were infected.

The period of incubation of cholera is so short that its transmission by infected individuals stands out with great distinctness, for, as a rule, these persons were sick at the time of arrival. For instance, the first cases at Dasmarinas, June 5, were members of the native constabulary who had spent June 1 at a village eight miles away in which cholera was present; while the first case at San Pablo was a native who visited for three days in Santa Cruz, where the disease had prevailed for two months, and who was taken sick twelve hours after his return, and died thirteen hours later. As the territory included in the investigation was under military control, with closed ports, it had been suggested that infected soldiers introduced the disease and started the epidemic; but careful investigation by a board of medical officers leaves no reasonable doubt that clandestine arrivals among the natives had introduced the infection, and that they were dying from cholera for nearly a month before this fact was more than suspected. This fact is still further demonstrated through the occurrence of the first cases of the disease among soldiers in men who had been in the districts recognized as being infected.

After the introduction of cholera, its spread from the first case usually occurred through the medium of water, though food infected by flies or dirty hands played a considerable part therein among the natives. Among the soldiers, the quality and preparation of the food in garrison was carefully guarded, the water was boiled, and nearly every case occurred as the direct disobedience of standing orders which prohibited the use of native foods or drinks and the use of unboiled water. One exception is the case of a company cook who had been in the habit of eating pieces of raw meat, and as the latter came through a cholera-infected district, on boats on which natives had died of cholera, it might have become infected by handling. Three cases occurring in the prison at Santa Cruz were believed to have been infected by food carried in by natives. In only one instance was the disease attributed to infected fruit, when five out of the six first cases at Lipa had eaten of the same pineapple. Where the infection seems to have been due to food or water, however, it is difficult to exclude the possibility of the use of infected water also.

The chief way by which the disease was spread locally was by drinking water contaminated with cholera excreta. For instance, the inhabitants of the town of Lucsuhin used water from a shallow stream running through the town. The first cases here were quickly followed by a violent epidemic, which killed nearly 25 per cent. of the population of 3,000, and which ceased after heavy and prolonged rains had swept the bed of the stream clear. Where there were many wells in a town, the epidemic was never as general or sudden in its development, as it is not likely that all the wells could become infected at the same time. Hence cases in such a town show a gradual instead of an abrupt increase. In San Fernando it was shown that the widely scattered early cases in the town all took water from a popular well, which could readily have been infected from a case in an adjoining house. Those natives of the better class who used the water collected from the tin or tile roofs of their houses largely escaped cholera. At Balayang, the severe epidemic was confined almost wholly to people in the part of the town using river water, which had been infected by the first case, while natives using the spring water escaped. Although water was undoubtedly the main source of infection, the extremely insanitary habits of natives made it possible for them to infect anything and everything, and rendered it very difficult in many cases to determine the method of conveyance. The carriage of cholera infection by flies seems to have been established in the case of the troops at Lipa, the latrines having been infected by the first cases. Direct infection from the sick, where proper antiseptic precautions were taken, proved to be rare, though cases occurred among soldiers detailed for cholera work. A feature of the disease noted was the great difficulty in securing truthful replies from the sufferer, so as to enable his infection to be traced. This was noted so frequently in natives as to be regarded as a racial characteristic; but the same feature, though in less degree, was observed in the white men attached, who could have had no reason for the concealment of any fact. Prevarication seems to depend upon mental apathy rather than a desire to deceive, and is perhaps dependent upon the altered condition and lessened oxygenation of the blood due to the withdrawal of its fluid constituents. Whatever its cause, this condition has proved a serious obstacle in the investigation of the source of infection in the provinces. An undoubted source of infection existed in association with native prostitutes; but this is not susceptible of proof, as it is never admitted. To avoid this, it was successfully ordered in San Pablo that every man should be put in quarantine under guard except while on duty. Finally, familiarity with the disease undoubtedly bred a certain contempt for it, while the knowledge of the protection afforded by a few simple precautions led to a knowledge of false security. Not a few cases occurred in which men deliberately exposed themseves to the chance of cholera by eating and drinking in native houses, though fully appreciating the danger of such a course. One of the men who thus exposed himself, and died as a result, was a graduate in medicine; five others were members of the hospital corps. One case of direct infection occurred in a medical officer, apparently as a result of making numerous post-mortem examinations of cholera cases.

With respect to the high rate of cholera among troops at certain stations, the report finds that this was due to inefficient management by commanding officers, to failure by commanding officers to carry out the recommendations of their surgeons, to failure by at least one surgeon to press his recommendations after they had been made and ignored, and to direct disobedience of departmental and post orders by enlisted men. In several instances the medical board did not hesitate to severely score the responsible parties. "It appears that the post surgeon has been guilty of weakness in his management of the cholera epidemic here. The records show that while he made a number of recommendations, these were not acted upon, and that he took the position that, having made these recommendations, he had fulfilled his obligation to the command. The only extenuating circumstances in the case of the commanding officer are that he was, in our opinion, both physically and mentally incapacitated for command of a post—a fact of which the post surgeon must have been acquainted. The record of thirty-two cases and fourteen deaths in the command . . . with seven cases and two deaths among the quartermaster's employees is sufficient evidence in itself of the general mismanagement of the cholera situation at this post. . . . The most marked feature of the epidemic was the unconcern with which the commanding officer viewed the situation. Though the command was one of the most severely stricken on the island, and though communications and recommendations were coming in regularly from the post surgeon, these were filed away, and no further action taken upon them." Certain officers did not seem to be impressed with the gravity of the situation; and it was found especially difficult, in the case of colored soldiers, to keep them from eating and drinking in the native houses. The presence of a large

proportion of colored recruits not yet accustomed to discipline made this task especially difficult.

Concerning the occurrence of eleven deaths in one company, it is stated that this "is merely the penalty of having raw recruits without a sufficient number of officers." Well-disciplined regiments largely escaped the disease, in spite of being quartered in badly infected towns. In several instances in which cases of cholera developed in a command, the application of proper measures successfully checked the threatened epidemic. The report says: "Lack of discipline causes results reflecting upon sanitaton, and medical officers must understand that they are just as vitally concerned in the discipline of a command as any other officer. The more they confine themselves to prescribing for individual patients, and neglect the military part of their work, in just that proportion do they neglect their duty to their commanding officer. Some military training is now a necessity for medical officers; they have too long been forgetful that they are soldiers."

The strength of the command in which this investigation was carried out was about 8,000, the deaths from cholera in this number amounting to 90, or a rate of 11.2 per thousand. Among the 990,000 natives, in the same territory, the mortality from cholera was estimated at 25 per thousand. If it be understood that the troops were surrounded with cholera foci, and that there were innumerable ways by which the disease might have been contracted, the result is not bad, and speaks, on the whole, of the faithful execution of the recommendations of medical officers. Formerly, under like conditions, in India, before medical officers were able to outline scientific prophylactic measures, regiments were almost destroyed. Nevertheless, it is theoretically true that not one of the ninety deceased soldiers should have died, and in most of these cases the contraction of the disease was due to careless or wilful disobedience by the soldier himself. Some cases of the disease depended upon the insufficient supply of boiled water carried in the canteen, and the failure to carry a reserve supply with moving troops. As a result, these drank unsterilized and infected water *en route*, after the supply in the canteens was exhausted. Among civilian teamsters, who were not required to carry canteens as part of their equipment, the death rate was 34.5 per thousand. The rate for white soldiers was 10.0 per thousand; for colored soldiers 23.0 per thousand. Among the natives, the village death rate from cholera varied from zero up to 250 per thousand, as at Lucsulin. The more the native town is spread out, the greater has been the difficulty of doing anything for the natives. It does not appear likely that the spread of the epidemic could have been markedly lessened except by quarantine guards on all roads, requiring the services of 25,000 troops, and four times the number of medical officers actually present. It is suggestive, as showing the great sanitary importance of discipline that at the two worst stricken posts there were no summary court proceedings instituted against any soldier, while in a large command which entirely escaped the disease around them, "the post commander has maintained a high standard of discipline, and has punished any violation of rules with as great severity as possible. He has had ten or twelve men brought before a summary court for violation of rules concerning cholera."

The conclusions drawn in the report are that careful quarantine is the most potent factor in checking the spread of cholera, and that the nearer this approaches absolute isolation the better. All persons should be held five days at point of arrival, and no merchandise admitted except in a thoroughly dry condition, and not liable to have been contaminated. Even an ineffective quarantine is regarded as better than none, as it delays the introduction of the disease and lessens the number of foci of infection. Prompt detection and isolation of the sick, with the disinfection of their discharges and surroundings, is essential. Treatment in hospital is desirable; in the hospital at Biñan the mortality was 40 per cent., while outside it was 80 per cent. Detention camps for contacts are not essential, as contacts do not seem especially liable to contract the disease. They should be quarantined in their own houses, so as to secure subsequent cases which have been infected from the same source as the first one. To avoid the loss of personal liberty from confinement in a detention camp, cases will be concealed by natives, and the system do more harm than good. The source of the disease should be traced when possible, and the specific cause destroyed at the source. The sale of fruits and vegetables used uncooked should be prohibited, and cooked food protected against contamination. Instruction in the necessary hygienic precautions should be given. Finally, for the military service, the accountability for sanitary deficiencies should be definitely placed upon either the surgeon or commanding officer, so that sins of omission or commission can be properly punished, and the guilty not be allowed to escape as a result of divided responsibility.

LETTER FROM NEW ZEALAND.

(From Our Special Correspondent.)

OKOROIRE, NEW ZEALAND, January 22, 1903.

I AM writing from one of our health resorts, in the middle of the North Island, which has been established on account of its hot springs. The place was recommended to me on account of its "bracing" qualities; I have not yet found them out, but as this is the hottest part of the year in our Southern hemisphere, perhaps that may account for it. Anyhow, the air is pure, the soil is porous, and there are no swamps about, so a city resident must find it an improvement on his ordinary environments.

We are undergoing an extensive epidemic of measles, which is generally attributed to the return of our troopers from the war in South Africa. The ship I returned in had a number of cases on board, and many more were taken sick after landing. The disease was unusually fatal among the men, owing to the overcrowded state of the transports, and the filthy state of the men. It appears from an investigation by a Royal commission that the space allotted by the Admiralty regulations was not quite filled up in any of the transports. This proves that the Admiralty regulations are wrong. To pack men in hammocks with only eighteen inches allowed in width is certainly not likely to conduce to health in men who have just come off the veldt, where they have slept in the open air, and had plenty of hard work. The men literally did nothing for the most part but eat, drink, and sleep. They had no amusements on our ship, except sports on one occasion, in which they showed how much out of condition they were. When attacked with measles, most of them developed pneumonia, of which many died.

We have also had an epidemic which some call gastro-enteritis and others English cholera. It is characterized by violent colicky pains, vomiting, and diarrhœa. There have been some deaths, chiefly amongst old people. This again the public charge against the returned troopers, although I don't see why. We have had much dysentery and enteric, but nothing like this gastroenteritis. I have not actually seen any cases, as I have been unable to practice since my return.

We still have a few sporadic cases of plague, but nothing to make a fuss about. There is one fatal case described in the report of the Health Department in great detail, in which I cannot but think the patient died more from the *nimia diligentia medici*, or, rather, *medicorum*, for he had three or four doctors, than from the disease itself. I think, considering how entirely inexperienced in the treatment of plague cases our medical men are, it would be better if they let the patients alone more, and adopted a simple expectant plan, with the wet pack to subdue fever. When a man is treated with Yersin's serum, calomel, hyocine ($\frac{1}{200}$ gr. hourly!), hypodermic injections of hydr. perchlor. into the bubo, painting the surface with ichthyol, whiskey and hypodermics of strychnine every four hours, potassii bromidum, and chloral, digitalin $\frac{1}{100}$ gr., hypodermically, every four hours, Yersin's serum again on the eighth day, chloralamide, bromide, injections of strychnine and digitalin, and Yersin's serum again on the ninth day. On the tenth the poor man had saline injections per rectum, Yersin's serum and stimulants four hourly as before, and yet he died early the next morning. If such a course of treatment were administered to a healthy man, I should think he would gladly die on the eleventh day

I saw an officer with exactly the symptoms from which this man suffered—bubo and high temperature not arising from syphilis, gonorrhœa, or any visible injury to the lower extremity, admitted into the Pinetown Hospital in Natal when I was there. The bubo was poulticed; he had little if any medicine; when fluctuation was established, the surgeon in charge incised the bubo, and let out a large quantity of ordinary pus, and when I left, the patient was convalescent. He was a Canadian. I said to him, when he was getting better, that it was lucky for him he had not landed in New Zealand, or he would assuredly have been treated as a case of plague.

Considering the experience of Sydney, and the proof that plague of the ordinary kind, not pneumonic, is not communicated directly from one person to another, it seems to me that the precautions taken are excessive, and must often prove fatal to the patient. Tell a patient he has plague, and you half kill him to begin with, just as the knowledge that a man is suffering from cholera is far more fatal than the disease itself. Every one who has had a large experience of cholera knows that. But our chief health officer has plague on the brain. Considering that the death rate of the colony is only about eleven per thousand annually, the Health Department must justify its existence.

Progress of Medical Science.

The Boston Medical and Surgical Journal, Feb. 19, 1903.

Observations upon Long-Distance Runners.—J. B. Blake and R. C. Larrabee report the result of the observations upon members of the Boston Athletic Association, taken by Drs. Williams and Arnold during the contest of 1899. The length of the course is twenty-four miles; the contestants were of various nationalities, and their ages ranged from sixteen years upward The pulse rate was always increased in frequency, though the increase was often surprisingly small. The loss of weight varied from two to seven pounds. After the finish, the mouth temperature was sometimes raised, often normal, and occasionally subnormal. The rectal temperature was invariably raised. The difference between mouth and rectal temperature was often surprisingly large—in one case as much as 7°. The men ran with open lips, and the forced and continuous breathing of cold air lowered the temperature of the mouth cavity. As to the urine, in every case an active hyperæmia is developed during the race. The amount of urine for twenty-four hours is lessened, the color becomes higher, the specific gravity rises, and the reaction becomes more intensely acid. Urea is diminished for twenty-four hours. Chlorides are markedly diminished after the race.

J. B. Blake and D. D. Scannel state that the pulse-rate seemed to depend on three factors; first the condition of the heart itself; second, the character of the exertion, particularly in the last few minutes of the race, and third the time which elapsed between the actual finish and the observation of the pulse. The hearts best prepared for the contest seemed to have the slowest rates. These hearts were always hypertrophied, but were not overworked by excessive training. As to temperature, the results showed that forced exertion of this character raises the body temperature. Other agents, acting simultaneously may cool exposed portions of the body. In rare instances the ingestion of large doses of alcohol seems to prevent the body temperature itself from rising.

Allen Cleghorn reports on the pulse tracings taken from the Marathon runners in the races of 1900, 1901, and 1902. The candidate invariably presented at the start of the race a normal pulse curve, but at the finish the curve was found to be profoundly altered, the tracing pointing to the condition of enormously low arterial tension. All competitors lost considerable weight during the race, presumably by loss of water through sweating, etc. The author queries whether the low arterial tension is a result of a concentration or lessening of the quantity of the blood circulating in the vessels, and consequently the vessels not being completely filled; or whether it is due to the action of the "depressor" nerve endeavoring to ease the overworked heart by increasing the caliber of the arterioles, and so lessening peripheral resistance, or to an active dilatation of the arteries caused by the circulation in them of fatigue products, CO_2, etc. He inclines to the belief that all these factors are concerned in producing this low tension pulse. Ralph C. Larrabee, Wilder Tileston, and W. R. P. Emerson, in their blood examination of contestants found a decided leucocytosis after the races. They suggest that it may be due to a double cause: muscular work acting mechanically to produce physiological leucocytosis plus a toxæmia from fatigue products acting chemically to produce toxic leucocytosis It has been amply proved that brief exercise produces an increase in all the forms of white cells alike, and one may assume that the cases here studied had such an increase during the early part of the race. Yet at the finish their leucocytoses were always characterized by a disproportionate increase in the polymorphonuclear neutrophiles. This result the authors are not able to explain.

Ralph C. Larrabee and Lawrence W. Strong in the races of 1901 found systolic murmurs before the race in six out of eighteen cases. They attribute these murmurs to nervous excitement. Out of these six cases the abnormal sounds had disappeared at the finish in four. After the race there was increase in the heart area in sixteen of the eighteen cases. They attribute this to temporary acute dilatation. It is difficult to understand that the heart should be dilated when the blood pressure is remarkably decreased. Stengel considers that the dilatation found in the presence of low blood pressure represents the failure of the heart to recover from dilatation that occurred in the early period of high tension. Another explanation is that the dilatation represents relaxation of the heart's muscular tonus as a result of exhaustion or "fatigue products." The authors hold that the changes, so far as the heart is concerned, must be considered as physiological.

John M. Connolly reports the results of the urinary examination. In most cases the amount of urine passed after the race was small. The color was in every instance higher; the acidity was increased. No satisfactory results were obtained in regard to the increase or decrease of the urea. Uric acid was diminished, as were the chlorides. Albumin was present after the race in every urine. After the race every sediment contained large numbers of hyaline and fine granular casts, a few coarse granular and epithelial casts. There was in all cases more or less blood, normal and abnormal, free and on casts. The amount of blood usually varied directly as the amount of albumin.

Journal of the American Medical Association, Feb. 21, 1903.

The Early Appearances, Diagnosis, and Treatment of Tuberculosis of the Upper-air Tract.—In the course of a general consideration of this subject, W. F. Chappell calls attention to the fallacy of a pale mucosa as a positive sign of laryngeal tuberculosis. In his experience reliance should be placed on recurring and persisting hyperæmias, infiltrations, and tumefactions. They appear as patches, or may involve the whole interior of the larynx. The interarytenoid space, ventricular bands, posterior third of vocal cords and epiglottis are the usual places for early circumscribed infections. Any of the enumerated symptoms, occurring in the situations described, should cause some anxiety and a careful watching of their progress, and especially so if pulmonary tuberculosis already existed. These symptoms may be present, however, without being tubercular even in a tuberculous patient. Cold, rheumatism, and voice strain will produce laryngeal redness and thickening, which may continue at intervals for years.

The Prophylaxis of Sinus Diseases.—D. Bryson Delavan notes that the prevention of sinus disease is not always within the limits of our present knowledge. Thus, in diphtheria, measles, and scarlet fever, attended as they are with violent local congestion of the nasal cavities, it is difficult to think of any safe means of treatment. In typhoid fever, smallpox, and pneumonia, however, careful systematic cleansing of the nasal passages is most valuable for many reasons, and is clearly indicated, not only for the prevention of otitis, but also for that of analogous inflammations of the accessory sinuses. We are, however, to proceed along the following lines: (1) We must recognize the conditions under which sinus inflammation is likely to occur, and if possible, remove them; (2) when removal of the predisposing causes is not practicable, we should guard the patient against the various exciting causes which may determine an acute attack, and (3) when acute inflammation is already threatened, we should apply immediate relief. This is found in two main procedures, through cleansing and free nasal drainage.

Medical News, February 21, 1903.

Functional Disorders of the Biliary Secretion and Their Treatment.—H. Richardson divides functional disorders of the biliary secretion into three forms—a morbid excess, a morbid deficiency, and a vitiation of the bile. A morbid excessive secretion of bile may exist theoretically, but there is little or no evidence that it ever produces any serious symptoms. Deficiency of bile, "torpor of the liver," is a much more common condition, producing morbid processes. The function of the bile is both excretive and secretive, thus if the formation is insufficient, failure of excretion will embarrass the liver, and failure of secretion will affect the digestion and absorption from the intestine, more especially the absorption of fats. It is certain, also, that at the same time vitiation of the bile formed takes place. Gallstones are of very great frequency, often producing very severe symptoms. Pregnancy and tight-lacing probably account for the greater number of gallstone cases among women than among men. In order to hold the excretory components of the bile in solution, and at the same time stimulate the gall-bladder to empty itself as often as possible to prevent stagnation. A purge of calomel and soda should be given occasionally to relieve the intestine of undigested food and possible toxins which may accumulate. The patient should drink a large tumblerful of water containing 5 gr. of sodium bicarbonate, about half an hour before meals, and an injection of a liter of normal salt solution every other day, well up into the colon, will be of great assistance. To increase the solvent powers of the bile, 5 gr. capsules of glycocholate of soda three times a day after meals will have the desired effect. If stone is present or suspected, the dose may be 10 gr. The diet should be abundant, principally of carbohydrates, but not excluding meats. Exercise is an important aid.

New York Medical Journal, February 21, 1903.

Intussusception in a Baby Five Months Old.—A case is reported by L. Fischer. Operation was refused by the parents and the child died. The most marked features of the case were the following: (1) continued vomiting; (2) fecal impaction, the gut being so obstructed that no fæces passed in more than ten days, though flatus occasionally passed; (3) during the first two or three days

not only was clear blood passed per rectum, but large masses of jellylike mucus, tinged with blood, were frequently expelled from the rectum until the end; (4) the distended belly, the abdomen abnormally distended and very tympanitic on percussion; (5) the absence of all inflammatory symptoms, such as rise of temperature until two days before the death of the patient, when the temperature rose to 101° F, and the pulse rose to 160°. (6) continued crying, the child, with rare exceptions, showed evidences of pain. The author regarded the case as a distinctly favorable one for operation, because the child was well nourished and developed, was breast fed, because an early diagnosis was made, and because there was a good heart action, and a freedom from any chronic or infectious disease.

The Prophylaxis of Appendicitis.—H. Illoway regards constipation as the great predisposing cause of appendicitis. It enables fecal matter to pass into the appendix, and the fecal matter thus forced and becoming stagnant may liquify and permit bacterial development which may give rise to an inflammatory process, either mild or severe. Fecal stagnation may also lead to formation of concretions. In answer to the objection that women are so generally constipated and yet more exempt from appendicitis than are men, Illoway makes reply: First, that in woman the pelvic cavity is much roomier than in man, and thus perhaps permits of greater distention of the cæcum without the orifice of the appendix being forced open. Secondly, that woman is more particular in her food, eats more at her home table, and is thus less liable to introduce decaying matter, which is likely to set up sharp putrefactive fermentation, into her digestive tract. Thirdly, she is not given so much to the free consumption of alcoholic beverages, which of themselves cause a predisposition to congestive processes in the abdominal organs, and particularly in the terminal parts of the intestinal tract. The general conclusion is—remove the constipation and there will be no appendicitis.

American Medicine, February 21, 1903.

Chronic Pancreatitis.—B. L. Hardin states that it is only about eighteen months ago that the true significance of this disease was brought to the attention of the profession. But it is not an uncommon disease. It is caused by infection, the toxic material usually gaining entrance through the pancreatic duct, sometimes through the general circulation. The patient may have suffered with long-continued chronic gastric catarrh. Suddenly severe epigastric pain occurs. This is central and not over the gall-bladder. It radiates either to the back and interscapular region or toward the left. After lasting a variable time the paroxysm recurs with either regular or irregular intermittence, or there may be no paroxysmal pain, merely a deep-seated dull ache. There may be nausea and vomiting. Diarrhœa or constipation may be present. In advanced stages glycosuria occurs. With each paroxysm the jaundice deepens. The pulse becomes slow; there may be hemorrhages from various mucous membranes or into the skin. The patient finally dies of exhaustion. On examination there is often a tender spot central and about an inch above the umbilicus. There is more or less resistance to palpation over the epigastric region, and very rarely the enlarged pancreas may be felt. In a few instances, when the enlarged pancreas passes on the vena cava, ascites develops. Diagnosis is very difficult. The best evidence of failure in pancreatic secretions is in the presence of an excess of undigested muscle fiber in the stools. Another good test is the absence of carbolic acid in the urine after the administration of salol. There is rapid loss of flesh and strength with the absence of marked anæmia and leukocytosis. When the urine from these patients is boiled with an oxidizing agent and the phenyl-hydrazin test applied, these results so far have shown a large number of delicate yellow needles, arranged in sheaves and rosettes. In many cases diagnosis can be made only by exploratory operation, which should be unhesitatingly done in all doubtful cases. The disease may last for months or perhaps years. The treatment is purely surgical, and is effected by clearing the ducts of obstructions so far as possible, and draining the gall-bladder or both ducts, as the circumstances may demand.

Philadelphia Medical Journal, February 21, 1903.

Retinal Hemorrhages; an Aid to the Early Recognition of General Arterial Degeneration.—Henry C. Haden concludes that: (1) Retinal hemorrhages, associated with high arterial tension and accompanied by transitory albuminuria, are significant of beginning widespread arterial degeneration. (2) That in those cases of so-called physiological or transitory albuminuria, occurring in active, healthy young business men or students, in those who are working under forced pressure, ophthalmoscopical examination should be made for retinal hemorrhages. (3) When retinal hemorrhages occur without albuminuria, the patient should be kept under observation, the urine to be examined from time to time and the quantity passed noted. (4) In case of finding these conditions, it is our duty to warn the patient of his condition and, as Osler says: "so gain his intelligent coöperation," and preserve his life and usefulness.

Uterine Carcinoma; Its Treatment by the Combined Use of the Finsen Light and the Röntgen Ray.—George G. Hopkins declares that, from his experience, he believes that the best method of treatment of uterine carcinoma consists in the combined use of decomposed light and *x*-radiance. The application of the light and radiance requires much thought and skill, the deposits being differently arranged in each case. With the Finsen light the external parts only need the protection of some fabric, but with the Röntgen rays we need metallic protection and, of all metals, lead is the most satisfactory. The patient is placed on her back and the rays so arranged that they will impinge upon the diseased surface. So far as the Finsen rays are concerned, they can play upon the parts for an hour or more, but with the *x*-ray it is different, the time must be limited and, when hysterectomy has been performed, more caution must be used, as their penetration cannot be limited, and there is no uterus back of the vagina to intercept and partly absorb the rays.

Tropical Abscess of the Liver.—Charles F. Kieffer speaks of three broad classes of abscess of the liver: Traumatic, pyæmic, and tropical. Traumatic abscess is usually solitary. It may arise from a severe contusion of the organ, without a lesion of the skin, or from the penetration of a foreign body, as a bullet, knife, or needle. The liver blood is relatively richer in bacterial forms than any other part of the circulation. The lesion in pyæmic abscess is usually multiple. It may begin in embolism of the portal vein from inflammatory lesions, affecting the radicles of the vein. Examples are ulcerations in the colon, appendicitis, hemorrhoids and, rarely, typhoid ulceration. Echinococcus cyst of the liver may suppurate and form abscess. In tropical abscess, the predisposing causes are first considered. There is a very great tendency to passive congestion of the liver, to some extent, in a large proportion of settlers in the tropics. Malarial, chill and exposure, and especially alcohol, are important predisposing factors. The writer thinks that alcohol in moderation produces no more harmful effects than in other climates. But its abuse is followed by a much prompter reckoning. The liver that is the seat of the beginning abscess formation, is congested and enlarged. There will be one or more areas of necrosis, the center of which will contain a few drops of bloody or chocolate-colored, inspissated pus. Later liquefaction takes place over the entire area. The abscess may be solitary or multiple. It varies in size from a pigeon egg to a cocoanut or even larger. Fever is the most constant symptom, and in type is hectic, of narrow range. Other symptoms are sepsis, enlargement of the liver and pain, although pain may be entirely lacking. Enlargement of the liver is fairly constant. The decubitus is quite characteristic. The patient lies almost on his right front aspect. The shoulder is drawn down and the right knee strongly drawn up to relieve the tension of the abdominal muscles. The prognosis depends upon the number of the abscesses and the time when the case is brought to operation. The diagnosis is quite difficult unless the abscess be large and the signs so prominent as to be unmistakable. In all obscure cases, attended with the signs of sepsis, insert an aspirator to make your diagnosis clear.

The Lancet, February 14, 1903.

An Unusual Number of Gallstones.—The patient of C. A. S. Ridout was a woman of forty-three years, whose condition called for a cholecystotomy. The cavity of the gall-bladder was found to contain 449 calculi, averaging about the size of a pea. Two more stones were passed during the period of convalescence. Recovery was without incident.

Note on "Relapse" in Scarlet Fever.—Three cases are reported by A. B. Slaan, who believes that the "relapse" is far more common than is generally believed. The statistics of the Metropolitan Asylums Board for 1901 show a percentage of 1.09 relapses out of over fourteen thousand cases. The histories of his own cases present nothing new.

A Rare Form of Purpura.—The case is related by H. L. Gordon, his patient being a boy of fourteen years of nervous temperament. The boy was suddenly taken ill, complaining of pain and stiffness in the limbs with a rash on the legs. There was no previous history of rheumatism. A diagnosis of purpura rheumatica was

made, but this was shown to be incorrect by the onset of colic and the escape of a pint of blood from the bowels. Joint swellings appeared later and the colic also returned. Various "flying œdemas" made their appearance in different parts of the body. This changing character of symptoms continued for some weeks when a loud systolic mitral murmur was heard. These purpuric rashes, flying œdemas, etc., lasted over the space of several months, and then a chorea set in. The case seemed to present a curious mixture of the symptoms of purpura rheumatica and the "peculiar purpura" described by Henoch, but the case differed from the clinical picture described by Henoch as follows: (1) In its more continuous nature; there were no intervals of freedom from symptoms of several days or weeks or even of a year; (2) in the prominence of skin eruptions other than purpura, and of what can only be called "flying œdema"; (3) in the cardiac complication; (4) in the chorea; and (5) in a diminished daily flow of urine. At last accounts the boy was fairly well but still nervous. No treatment seemed to have any curative value, and symptoms were relieved as they arose. An earache preceding by a few days the onset of his illness, was suggested as a source of septic infection, but this could not be proved. The poison, whatever it was, seemed to expend itself on the nervous system.

Notes upon a Case in Which Symptoms of Early General Paralysis of the Insane Followed a Head Injury.—The case is reported by Marmaduke Shield and T. C. Shaw. The patient was a man of thirty years. At the time of operation his condition was as follows: He had a confused and demented facial expression and had a considerable amount of both facial and general tremor. He complained of pressure-feeling over the scalp and declared his inability to perform any sustained mental work. There was no disease of the fundus oculi, but the pupils were slightly non-symmetrical, the left being the smaller; they reacted to light and accommodation. He could not stand firmly when his feet were placed together, nor could he walk along a line when told to plant one foot directly in advance of the other. The knee-jerks were present but weak. There was some tremor of speech, but the tongue was fairly steady, and there was no prominent complimentary spasm of the muscles around the orbit. When asked to read the paper he misplaced and mispronounced words and altered the spacing. The handwriting was to be deciphered with difficulty, owing to the crowding of the letters and shakiness of the upstrokes. The prominent mental condition was one of dementia, an apathy and slowness of comprehension in answering ordinary questions. There was an unwarranted sense of *bien-être*, but no illusions could be elicited. The friends said that he had become subject to impulsive outbursts, and was considerably changed in general disposition. He suffered from insomnia and spoke of loss of sexual appetite. As to diagnosis there was no history of alcoholic excess or of syphilis, and the symptoms appeared to be directly traceable to an injury to the head. It was probable that they were due to pressure, and the only remedy seemed to be to resort to trephining as soon as possible. The temperature under the tongue was 100° F. The operation consisted of reflecting a semilunar flap over the left frontal region, the site of the injury following his being thrown from a wagon three months previous to his coming under observation. A faint crack was discoverable in the bone, though none had been made out at the time of injury. Trephining showed that there was pressure on the dura. The bone was lifted and the operation concluded in the usual manner Two days later improvement began in the mental condition, and at the time the case was reported there was every reason to believe that the man would completely recover.

British Medical Journal, February 14, 1903.

Frambœsia in Fowls.—Jas. A. L. Calder states that the histological features of the disease in fowls are identical with those seen in the human variety. The disease attacks chickens mostly, and its chief seat is the head. The disease thrives best in the young. The writer has not been able to transfer the disease from man to fowl, nor from fowl to man. However, he believes that the diseases are identical. Frambœsia is not syphilis.

Cerrebellar Hemorrhage in a Girl Aged Nine and a Half Years.—H. H. Phillips was called to see this case after the child was dead. On that morning she was apparently perfectly well and ran upstairs. But on coming down she complained of headache. In fifteen minutes she was asleep. This sleep deepened into coma, and death occurred in half an hour. Necropsy revealed a large hemorrhage, which had practically excavated the entire left lobe of the cerrebellum. The right lobe and cerebrum were normal. The lesion was quite recent, and the cause of the hemorrhage could not be determined.

A Case of Prolapsus Uteri Treated Successfully by Injection of Quinine.—G. Crewdson Thomas reports the case of a woman of thirty-eight years, who looked strong and healthy, and had had three children. The vaginal walls were very lax, and the uterus was enlarged and retroverted with a soft and hypertrophied cervix. On straining, there was marked procidentia. The writer instituted the treatment of injecting the broad ligaments with quinine sulphate solution (50 minims in each), and replacing the uterus with the insertion of a Napier's pessary. At the end of the third week a Hodge pessary was inserted, and the patient was allowed to get up. The results were most satisfactory. Three months later there was no tendency to prolapse of either the vaginal walls or uterus on straining.

Operations for Cancer of the Tongue, and the Early Diagnosis of the Disease.—H. T. Butlin lays down the following rules for guidance in regard to operations on cancer of the tongue. He first discusses warts and warty growths, particularly on tongues which are the seat of one of these predisposing conditions. No time should be lost in removing these growths. It should be done by two elliptical incisions which include the healthy tissues around the wart into the muscular substance. The edges are brought together, and the wound is healed in four or five days. In regard to indolent ulcers upon the surface or under the border of the tongue, which are ascribed to the rubbing of a tooth, the cause of the irritation should be removed at once. And if, at the end of a week or ten days from that time, the ulcer is not well or healing rapidly, it should be cut out in precisely the same fashion, with not a moment's hesitation. The operation is trivial, and may save the patient from great misery, and often from a horrible death. If white patches or plaques become thicker, and a little more prominent, and particularly if they show a tendency to break down in the center, or soften, they should be cut with as little delay as possible. The writer now, in cases of bad superficial glossitis, when the tongue is constantly irritated, and the patient always suffering and in dread and danger of cancer, removes that part of the tongue, even when there is no sign of cancer or of a precancerous condition. This holds true especially when the under surface is in a healthy condition, so that the mucous membrane can be turned up to make a good covering for the stump Such patients are then relieved not only of the fear, but of the danger of cancer. They are able to take all kinds of food which had been previously denied them on account of the constant irritation which such food produced.

A Contribution to the Study of Cancer Mortality.—Charles Templeman concludes, as regards cancer in the city of Dundee: (1) That the death rate from cancer as a whole during the twenty-five years under review has more than doubled, having increased from 7.27 to 16.92 per 10,000 of the population over the age of twenty years. (2) That this increase is greatest at ages over forty-five, is common to both sexes, but more marked in the male sex, though the actual mortality is higher among females. (3) That in females this is chiefly due to an increase in malignant affections of the abdominal viscera. (4) That uterine cancer and cancer of the breast in females have increased, though not in any marked degree. (5) That cancer of the rectum also shows a slight increase in both sexes. (6) That in males the highest mortality is from cancer of the abdominal viscera. (7) That in males cancer of the mouth and upper digestive tract has also greatly increased. (8) That, therefore, cancer of regions which may be described as "accessible" has increased as well as that of parts which are not so accessible, and where the diagnosis is more difficult, but the increase in the latter is out of all proportion to that in the former class. (9) That during the same period there has been a great improvement in both clinical and pathological diagnosis, as well as in death certification, and consequently a considerable diminution in returns from such indefinite conditions as "old age" and "disease" of the various organs (without any specification of its nature). (10) That this must, to a considerable extent, have helped to swell the returns of death from "cancer." The writer does not think this sufficient to account for the great increase of cancer mortality. This increase is real and substantial, though not so great or alarming as the general public believe. To solve this problem of increase, we must have a more accurate knowledge of the etiology, and if parasitic in its nature, we must know something of the life history of the organism which gives rise to it.

Munchener medicinische Wochenschrift, January 27, 1903.

Serumtherapy of Exophthalmic Goiter.—Otto Lanz adds four cases to the two which he has previously reported. All were well marked cases of Graves's disease, and one was far advanced when first coming under treatment. To all the so-called "milk treatment" was given—that is, the

milk of thyoidectomized goats. The duration of the treatment was varied, being from several weeks to six months In every case treated the result was satisfactory, marked improvement taking place in the special symptoms. It should be noted, however, that this disease is subject to marked variations in its clinical course, and that the number of cases as yet treated by any system of serumtherapy is too small to admit of definite conclusions as to the actual value of such a method of treatment.

Scarlatinal and Diphtherial Nephritis.—O. Heubner shows that pathologically these forms of nephritis are different and may be easily differentiated. Scarlatinal nephritis shows marked hemorrhagic changes, especially in the glomeruli. The involvement of the epithelium is secondary. In diphtheria the renal lesions are primarily epithelial. Hemorrhagic lesions are sometimes found, but never involve the glomeruli, as in scarlatina. When present they are almost always found in the region of the straight tubules. In preparing the tissue for examination it was first placed in 10 per cent. formalin solution for twenty-four hours. Frozen sections were then made. These were stained with hæmatoxylon and decolorized with hydrochloric acid and well washed. They were then placed in dilute eosin solution for several hours and again in water for twenty-four hours. The number of scarlatinal cases studied was only two. This was because of the great difficulty experienced in obtained pure cases of this disease, since the vast majority of those observed showed the presence of diphtheria bacilli in the throat.

Münchener medicinische Wochenschrift, February 3, 1903.

Gangrenous Pharyngitis and Appendicitis in Combination.—W. Mayer reports this case in support of the theory that pharyngitis frequently holds a direct etiological relation to appendicitis. The patient, a female seven years of age, suddenly developed pharyngeal symptoms of great intensity. Examination showed a marked injection and swelling of the tissues, but no membrane. Diphtheria bacilli were not found. Within twenty-four hours the lesions became characteristically gangrenous in appearance. At this time abdominal symptoms (pain and vomiting) appeared. Examination showed a tumor in the right iliac region, and McBurney's sign positive. Upon operation a perforated gangrenous appendix was found. Recovery took place. Microscopical examination of the pharyngeal secretion showed a few bacilli and staphylococci and a great abundance of streptococci. In the appendix only colon bacilli were found. The author does not think that this diversified bacteriological find is to be regarded as against the close association of these processes, since the colon bacilli in the appendix may have "overgrown" the streptococci which gave rise to the trouble.

Acute Cerebral Ataxia.—Adolf Bickel reports a rare case of uncomplicated acute cerebral hemiataxia. The patient was a male, sixty-four years of age. The previous history was good. In May, 1902, he was suddenly seized, while walking, with marked attack of vertigo. Consciousness was not lost. When seen shortly thereafter all of the senses were intact, but there was a marked loss of cutaneous sensation over the entire left half of the body, including the face. The line of demarcation between the affected and non-affected was sharply drawn at the median of the body. All the movements made by the patient with his left limbs were markedly ataxic. If the patient closed his eyes these limbs could be placed in various positions without his knowledge. The majority of the reflexes on the left side of the body were accentuated. Babinski's reflex was absent on both sides. Also the foot clonus was bilaterally absent. Both pupils were normal. There was no laryngeal paralysis. The muscular power on the affected side was not in the least reduced, and the electrical reaction of the muscles and nerves was normal. During the following six months the condition slowly improved. The movements of the infected side became less ataxic and more spastic in character. At present the patient remains in *statu quo*.

Deutsche medicinische Wochenschrift, January 29, 1903.

Epithelioma Contagiosum of Fowls.—E. Marx and Anton Sticker a few months since demonstrated that this disease was readily transferable from doves to hens, but not *vice versa*. In a new series of experiments they have inoculated hens from doves, and then inoculated other doves with virus obtained from the infected hens. They find that in the latter doves the virulency of the virus is much reduced. Of eighteen doves thus treated, seven showed no signs of the disease, three had an abortive attack, five had a mild attack, while in only three was the infection well marked. Thus are established similar relations as are present between variola and vaccina, and there is developed a new method for the control and mitigation of "bird pox."

A Case of True Hermaphroditism.—Garré describes a case which he recently exhibited in Konigsberg. The subject was a Russian, twenty years of age, and had always passed as a male. The penis was fairly well developed, but contained no urethra. The vulva was characteristically formed and of the usual size. Menstruation occurred regularly every month, but the flow was always scanty. With the patient's permission the lower abdominal cavity was opened on the right side just above Pourpart's ligament. An ovary and fallopian tube of fair size were found and immediately below a testicle. These structures were removed and examined histologically and the diagnosis thus absolutely confirmed. So far as is known this is the first case of true hermaphroditism which has been confirmed by both macroscopic and microscopic examination.

Mechanism of Strangulated Intestine.—Wilms gives the following description: When a small knuckle of intestine has slipped into a narrowing there is no strangulation at once and fecal matter enters the knuckle through its upper entrance. It enters, however, with more or less difficulty according to the pressure exerted upon the knuckle and the size of the incarcerating ring, and passes out of the lower entrance with still greater difficulty. In a varying length of time fecal matter, therefore, begins to accumulate at the lower end of the knuckle and thus distends the intestine in this location. This distension causes a drawing up of the intestine at the lower end of the knuckle, so that more is drawn into the ring at that point; as this increases the amount of fecal matter accumulates in the knuckle; pressure and tension increase, and strangulation takes place. Diagrams are submitted which make the author's description entirely clear.

Berliner klinische Wochenschrift, February 2, 1903.

Incipient Tabes.—Georg Flautau emphasizes the importance of a consideration of all the symptoms in the early diagnosis of tabes. Various observers have laid great weight upon the diagnostic importance of special symptoms, but it is certain that most of these may fail in incipient tabes, and, on the other hand, be occasionally observed in other conditions. The absence of the Achilles reflex when Babinski's method is employed is of considerable value for the diagnosis of tabes; nevertheless, experience has shown that it is not to be absolutely relied upon. One hundred cases of non-organic nerve cases showed this phenomena with Babinski's method bilaterally absent in two and unilaterally absent in two. The triceps phenomenon is of much less value since this is frequently absent in purely functional cases. In advanced cases several of these special signs are of great diagnostic value, but for the early diagnosis of the disease a consideration of the entire clinical picture, together with the personal and hereditary history, leads to more correct results than a dependence upon any special symptom.

Value of Otitic Symptoms in the Diagnosis of Cranial Injuries.—Stenger says that in recent cranial injuries objective otitic symptoms are of certain value in locating the seat of the lesion. The discharge of cerebrospinal fluid from the ear means, as a rule, that basal fracture is present, while the discharge of blood from the same orifice unless accompanied by a distinct external fracture is of very little, if any, value in this connection. The same may be said of rupture of the tympanum as of the discharge of blood. Functional otitic symptoms may be utilized to great advantage for diagnostic purposes in both recent and late cases. Such symptoms may be divided into three groups: (1) Loss or disturbance of hearing; (2) vertigo; (3) paralytic appearances. Simple loss of hearing means an injury in the region of the origin of the internal auditory nerve. Loss of hearing combined with paralysis of the facial nerve means an injury to the internal auditory nerve at some point in its course. Loss of hearing combined with vertigo means an injury to the internal auditory nerve in the region of its peripheral distribution. Loss of hearing may be tested either by whispered speech or the tuning fork. Disturbances of hearing mean an injury either to the labyrinth or to the middle ear. Vertigo when alone present signifies an injury to the semi-circular canals. Of course it is to be understood that the entire significance of vertigo in this connection depends upon its relation to some cranial injury—that is, it must have been preceded by such an injury within a reasonable time. Unilateral nystagmus is often associated with injury of the semicircular canals of the affected side. Paralysis of the facial nerve is the only paralytic symptom which directly accompanies injuries of the internal ear. By a combined consideration of the above symptoms much light may be thrown upon the location of the lesions in many cases of so-called traumatic neuroses, and a sharp differentiation may be made between those in which actual lesions are present and those in which the entire process is one of simulation.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held February 9, 1903.

ROBERT T. MORRIS, M.D., CHAIRMAN.

Intestinal Obstruction; Gastroenterostomy.—Dr. SAMUEL LLOYD presented, in connection with his paper, a woman who had come to him at the Post-Graduate School. She had already had a ventral fixation done, and thirteen months before admission had been operated upon for appendicitis. She complained of nausea, epigastric pain, and vomiting. Pressure below the ribs on the right side caused excruciating pain. Examination of the stomach showed hyperchlorhydria. The vomitus had never been streaked with blood. He saw the patient with Dr. Quintard in October, 1901, and the case was decided to be one of intestinal difficulty, possibly of obstruction. On November 2 he made an incision on the right side. The stomach was found to be greatly dilated, with its pyloric end drawn down a considerable distance. From this point the pylorus was bent upon itself and ran upward and inward. The smaller end of the stomach was thus drawn out into a tube, and was bent upon itself in the shape of a letter "S." This extreme flexure caused partial obstruction of the lumen of the pylorus. The cæcum was found to be normal; the appendix was gone. The gall-bladder appeared to be normal, and no calculi could be felt on palpation. With great difficulty adhesions between the stomach and intestine were gradually broken up by the fingers, and the colon was straigthened out. The uterus was found to be held in good position by a band one inch and a half long. An attempt was made to fasten the pyloric end of the stomach into position by freshening the peritoneum in the hope of getting adhesions. This, however, failed, and the patient soon began to complain again of the same symptoms. The second operation was done on the left side. This disclosed the fact that the pylorus had been drawn down again, and was sharply flexed as at first. This time a gastroenterostomy was done by McGraw's method. The patient was comfortable for some months after this, but returned to them with all of the old symptoms. Palpation seemed to indicate the advisability of not operating, and after the patient had been in the hospital for some time she recovered, and since then had done well up to within the past few weeks, when the vomiting had returned. He would like to hear the opinions of others regarding the advisability of further operation.

Dr. JOHN F. ERDMANN said that he did not think there was much occasion for operation at the present time, her condition, apparently, being largely the result of a neurosis or of her hysterical state.

Dr. R. T. MORRIS said that there could be no doubt that the mental feature in some of these cases was quite prominent, yet most practitioners did not feel like referring their patients of this class to those who applied themselves systematically to the relief of the psychical element.

Dr. LLOYD said that he concurred in the opinion expressed by Dr. Erdmann, and had already advised against farther operation. As long ago as last June she had been treated in the hospital by suggestion, and had been temporarily relieved. It was, of course, possible that at some time the intestinal adhesions would give rise to obstruction, necessitating an operation.

McGraw's Operation for Gastroenterostomy.—Dr. SAMUEL LLOYD read a paper on this subject. He said that in stomach operations particularly the Murphy button had proved very disappointing. In some cases the necrosis of tissue between the flanges of the button extended beyond the line of sutures, and caused fatal extravasation; at other times the button became impacted after leaving the stomach. The author said that so far he had employed McGraw's method only seven times, but even this experience had convinced him that it was efficacious, rapid, and easily applied. The weak point of the operation was the danger of breaking the ligature. The stomach having been brought into the wound, the position for the anastomosis was selected, preferably on the posterior wall whenever possible. The operator should seek for the junction of the duodenum and jejunum, and the latter should be followed downward for sixteen or eighteen inches, and an opening then torn in the transverse mesocolon, and the posterior wall of the stomach drawn through so as to expose the surface for about three inches. The jejunum should then be attached to its upper surface about one-half inch from its free surface. A simple Lembert stitch was carried along the portion of the gut required for the anastomosis. A sterile rubber ligature threaded into a needle was next passed through the stomach wall, and then through the intestine. This was best done by pressing the stomach wall together over the whole area to be included in the suture, and while the assistant held the rubber taut the surgeon passed the needle and drew it through the stomach wall. In order that the exposed viscera might not be soiled by the rubber, the stomach was covered with gauze or a towel. As soon as the tension on the rubber ligature was released the ligature expanded and completely closed the orifices of entrance and exit. The intestine was next treated in the same way. A piece of strong silk was now laid along the line of sutures before the rubber suture was tied. The rubber should be tied over the silk, and then the silk tied over the knot of the rubber. The silk and rubber were then cut short. This procedure caused distinct puckering of the stomach and intestine together. McGraw said that at first he feared the folds might become agglutinated together, and be held permanently corrugated, but this fear proved to be unfounded. Another danger at first apprehended was that the ligation and folding of the intestinal wall might cause irritation or obstruction of the gut, but this was found not to occur. The symptoms following operation appeared in no case to depend upon injury to the intestine. Coming back again to the line of Lembert's stitches, it should be said that this line was finally carried over the rubber stitches. In order to be successful it was important to select a proper rubber ligature. According to McGraw, the ligature should be a hard, round, and smooth cord at least 2 mm. in diameter, but the speaker thought it would be better to have the ligature still larger. The rubber ligature must be drawn as firmly and tightly as possible without breaking, and tied by a silk knot. In this operation there was no incision of the bowel, no loss of blood, no escape of fæces, and no exposure to peritoneal infection by escape of the bowel contents. The operation was followed by a minimum of shock and pain, and the patient recovered rapidly without any sloughing of the bowel. The advantage of the method over the Murphy button was that the surgeon could make the opening large or small as seemed best. Feeding might be begun after forty-eight hours, although McGraw advocated an interval of fifty-six hours.

Dr. LLOYD said he had been able to collect eighteen operations performed by this method. Three of them had been done by Dr. Willy Meyer, with one death; three by Dr. H. O. Walker of Detroit, all successful; five by Dr. McGraw, with two deaths from collapse—one from starvation and one from vicious circle, and his own seven cases without any fatalities. In McGraw's cases, only the first fatality could fairly be attributed to the operation. In his own seventh case, owing to the breaking of the ligature the operation had to be completed by suture. This record gave eighteen cases performed by the McGraw method with one failure of the ligature and five deaths. Three of the deaths would have occurred by any method that could have been employed. The

operation was certainly exceedingly simple and effective, and required little time for its performance.

Dr. Willy Meyer said that on reading the description of McGraw's method he had been impressed with its merits, and had given it a trial at the first opportunity, although he had long been a warm advocate of the Murphy button. He preferred to use for the rubber ligature the ordinary rubber ligature, size No. 4. There seemed to be no necessity for having the ends made tapering. The cases operated upon by him according to this method were then briefly described. The enteroenterostomy he had modified by using the continuous suture, but this was not recommended for the stomach because of the different thickness of the wall of the stomach and that of the intestine. With regard to the vicious circle, he would say that he had never seen a single fatality result from the vicious circle, but he had suggested the use of enteroenterostomy in connection with the use of the elastic ligature. It was probable that in the future the method adopted would be to unite the anterior wall of the stomach to the duodenum, taking pains to liberate the duodenum sufficiently to make it movable. If this mode of operating were adopted he thought the McGraw method would be found especially useful. He had not seen any specimen yet showing the condition of the bowel after the McGraw operation, but his own patients had been so free from digestive disturbance that he had no doubt the opening remained of the original size. He considered the McGraw method a very great addition to our technique.

Connell's Suture.—Dr. George Gray Ward spoke of the Connell suture for intestinal anastomosis, illustrating his remarks by diagrams. He said that one of the features of the Connell suture was that all of the coats of the intestine were perforated by the suture, and all of the knots were on the inside of the bowel when the operation had been completed, thus doing away with the objection of having the stitches on the surface. This was accomplished without the longitudinal incision used in the Maunsell method. Connell had pointed out that in the duodenum the glands of Lieberkühn were located in the submucosa, and hence, in picking up the submucosa these glands must be penetrated. The first stitch should be passed at the mesenteric border and completely through the walls of the bowel, then over to the opposite side and back again in the same way. This straddled the mesenteric attachment, and thus closed the triangular space. The second stitch was passed one-third of the circumference around the bowel. These two stitches were then tied and held by an assistant. The sutures placed between these two sutures were passed rapidly by perforating both walls of the intestine and tying in such a way that for every two perforations there was only one knot. The second third was sutured in the same way with stay sutures introduced as were the first two sutures described. The last third of the circumference must be sutured in a somewhat different manner because of the small space. The stitches bore the same relation to the walls of the intestine, but were passed through each coat separately. The trick of the method was in tying the last stitch. A threaded needle was passed—eye-end first at a point near the mesentery in the space between two stitches which had been previously tied. The needle passed into the lumen of the bowel and out through the small opening left where the last stitch remained to be tied. The ends of the stitch were caught in the loop of thread in this needle. The method of tying this last stitch was difficult to undertand from mere description without an accompanying diagram.

Harrington's Method.—The speaker also described a comparatively new method known as Harrington's. In this the anastomosis was made over an aluminum ring made in four segments. After this had been done the withdrawal of the handle of the ring caused the segments to fall apart—in other words, it was a form of crushable ring.

Dr. Edward Wallace Lee said that while he had had no personal experience with the McGraw method it did not appeal to him. One of the advantages claimed for it was freedom from soiling the peritoneum, but he was disposed to doubt the truth of this statement. One who was expert in the use of the intestinal suture should be able to complete the suture in from fifteen to twenty minutes; hence there did not seem to be much saving in time. He thought gastroenterostomy should be made on the anterior portion as far back and as low down as possible. At least four inches of the jejunum should be attached to the stomach, which, in itself, would have a tendency to prevent kinking. He was in favor of a continuous suture, the first past through all the coats of the intestine, and the last being a Lembert suture. He had not heard any one say yet what became of the rubber ligature in the McGraw method. It was said that the partition between the stomach and the intestine did not slough through, but was absorbed; possibly there might be a failure in this essential part of the operation, and the communication between the stomach and bowel not be established after all.

Dr. Robert T. Morris said that there were some points in Dr. Lloyd's statistics which required elaboration. For instance, Bevan, in analyzing 195 cases of union between the stomach and bowel in cases of cancer, found that the death rate was about 26 per cent. Heidenreich, in a series of about one hundred cases, operated upon for stenosis of the pylorus for ulcer, found the death rate to be about 16 per cent. from operation. Dr. Lloyd's seven cases with no deaths constituted a remarkable series, but it was most important in considering the death rate to determine the state of each patient and the particular condition for which the operation had been done. Dr. Mayo had said very truly that there were four questions to be decided at the present time in making a gastroenterostomy, viz.: Should one employ the anterior operation, the posterior operation, the button, or the suture? Although Dr. Mayo had had a very large experience in this field, he was of the opinion that it was not a matter of much importance which operation was selected so long as it was well done.

Dr. Lloyd, in closing the discussion, said that the foreign body left in the intestine in the McGraw method was so very minute that it was entirely a negligible quantity. It had certainly given rise to no discomfort. With regard to the question of how the communication was produced, the speaker said he was of the opinion that it was the result of a cutting or sawing action of the rubber ligature, and was not due to absorption. There seemed to be no doubt about this cutting through of the tissue taking place if the rubber ligature were drawn sufficiently tight at the time of operating. Aside from the simplicity and rapidity of the operation, it seemed to him that its greatest merit was the ability of the operator to make the opening just as large as seemed to be required in the individual case.

Periduodenal Abscess Secondary to Ulcer of the Duodenum.—Dr. William S. Bainbridge presented this paper with a report of a case. He said that he had been able to find only twenty-seven cases on record. Of this number twenty-two died without diagnosis. In the case reported by the author, the patient had been in good health, and the trouble had been suddenly ushered in by severe symptoms. These were relieved for a short time, and the patient became quite ill, and grew progressively weaker, finally dying in the eleventh week. The diagnosis of perforating ulcer of the duodenum was made, and operation advised, but consent could not be obtained. The autopsy showed a perforating ulcer of the duodenum one-quarter of an inch in diameter, and a periduodenal abscess. The author said that a study of the literature showed only eleven cases in which data were given with sufficient fulness and accuracy to be of service. It was pointed out that when the perforation was in the first

portion of the duodenum the chances were largely in favor of the production of general peritonitis; if in the second portion, the general peritoneal cavity would be walled off for a considerable time by newly-formed adhesions. Perforation of the posterior wall would give rise to retroperitoneal abscess. The anterior wall of the upper horizontal portion was said to be the most frequent site of the perforation. When the latter involved the general peritoneum it was usually acute. The most frequent symptoms were vomiting, pain, tenderness, and resistance in the epigastric and right hypogastric regions, constipation, or obstipation, sudden onset, and shock. Many of the patients could not lie on the right side because of the pain. Usually there was a history of gastric or intestinal disturbance. Melæna and hæmatemesis were not common; they occurred more frequently in ulcer than in abscess. As a rule, if there was any elevation of temperature it was slight, although, of course, fever might occur as a result of various complications. It was found far more frequently in the male than in the female, and occurred at all ages. The conditions which should be thought of were: empyema, pleurisy with effusion, cancer of the pylorus, pyopneumothorax, hydatid cyst, intestinal obstruction, disease of the gall-bladder or its ducts and appendicitis. The diagnosis was always difficult. Exploratory laparotomy should be resorted to when there was a probability of abscess being present.

Additional Cases Reported.—Dr. JOHN F. ERDMANN said that the subject was particularly interesting to him because he had seen five cases altogether. Three weeks ago he had operated upon a case of perforation of the stomach within one-quarter of an inch of the pyloric orifice, which practically brought it into the same field. In the two cases reported in an article by Weir and Foote, the perforation occurred within a week's time in his service at the Gouverneur Hospital. In none of the cases that he had seen had there been any history preceding the perforation which pointed to any digestive trouble. The first case was that of a robust Irishman who was seized with sudden abdominal pain. His abdomen was opened under the diagnosis of appendicitis. It was found to be filled with grumous material, containing some specks resembling pepper. He died in thirty-six hours. The second case was that of a healthy Italian who also had sudden and severe pain, and was subjected to operation for appendicitis in forty-eight hours. In both cases the duodenal ulcer was exactly the same. The third case was that of a man of about forty-two years of age, who came to the hospital with some indefinite abdominal disease. The perforation was found here also within one inch of the pylorus, and on its upper and anterior aspect. It was very easily reached by operation. The fourth case occurred in a woman of fifty-four years, who was practically moribund at the time of doing an exploratory laparotomy. There was general peritonitis. There was a very large perforating ulcer of the duodenum. The fifth case that he had seen, and which did not really come under his own observation, was observed in the dead-house of the hospital. The subject was an Irishman who had died almost immediately after admission. There was a history of illness for three days with sudden and severe pain. From the history duodenal ulcer was suspected, and this was confirmed by the autopsy. The speaker said he was of the opinion that a fairly definite diagnosis could be made in many of these cases; that is, the diagnosis would rest between perforation at the pyloric portion, perforation of the duodenum itself, or perforation of the gall-bladder. He thought acute pancreatitis could be entirely excluded. Attention was called to the fact that four out of his five patients were males.

Dr. C. CARMALT said that he had seen three cases. In all of them there was an abscess, and in two the diagnosis was made. One was a female child with a history of indigestion of about two months' standing; the other two patients were women. In the last case there was considerable nephritis; in one of the others there was pus in the urine and extensive disintegration of the kidney was present.

Dr. BAINBRIDGE closed the discussion. He said that the reports just presented seemed to indicate a confusion of periduodenal abscess with perforating ulcer of the duodenum. Dr. Erdmann had been very fortunate in finding these acute cases, and while they might have become periduodenal abscesses if these persons had lived long enough, the cases could hardly be considered as coming within the scope of his paper. The literature showed very plainly that if a careful history were taken it would be found that previous digestive disturbance was common.

Self-holding Retractors for Use in General Surgery.—Dr. W. S. THOMAS exhibited a simple retractor of this kind that he had devised. It was made of steel spring wire, nickel plated, bent to three-fourths of a circle. It was useful in office practice, and took up no room while in use. It was, of course, not claimed that such a retractor was equal to a trained assistant, but such assistants were not always at hand. The different sizes made gave the necessary variations in the strength of the pull.

A Coring Instrument for Operating upon Varicose Veins.—Dr. FREDERIC GRIFFITH presented this unique instrument. It was a surgical instrument acting upon the principle of the homely tool used for coring apples and other fruit, and was intended for use in connection with the subcutaneous operation for varicose veins. He said that in the removal of the saphenous vein, for example, it was only necessary to make two incisions and then apply this instrument. Traction on the vein made in this way caused laceration of the branches of the vein and allowed of their removal without any bleeding which could not be controlled by bandaging.

SECTION ON PEDIATRICS.

Stated Meeting, Held February 12, 1903.

HENRY HEIMAN, M.D., CHAIRMAN.

Report of a Case of Purpura Fulminans, with Findings of Bacteriological Examinations.—Dr. C. G. KERLEY made this report. The patient was a child seen in the country in consultation. The eruption was most abundant on the hands, wrists, and knees, but was also scattered over the arms, thighs, and feet. Blood was effused under the skin, and there were hæmatemesis and melæna with bleeding from other mucous membranes. The emaciation was extreme. Death in collapse terminated the case. Cultures were taken from the center of the blood clot in the nose and from the serum of one of the hemorrhagic areas under the skin, and from the knee. These cultures were examined by Dr. Martha Wollstein, who reported that the culture from the nose showed a pure growth of staphylococcus pyogenes aureus; that from the serum showed the same growth, together with a contamination, and the cultures from the knee also showed a pure growth of the same staphylococcus. Some of this material was injected into the peritoneal cavity of a medium-sized guinea-pig, and the animal died within twenty-four hours. Microscopical examination showed the epidermis from the deeply-pigmented skin to be normal. The capillaries in the papillæ of the corium contained hyaline thrombi. There was no evident site for the entrance of the infection.

Dr. HENRY KOPLIK said there had been two cases in his hospital wards, and cultures taken by Dr. Libman gave absolutely negative results. The cultures taken in Dr. Kerley's case could hardly be expected to yield scientific results because they came from contaminated areas, and some of them were removed post mortem.

Dr. H. W. BERG commented upon the great similarity in the purpuric symptoms presented by this case and those observed in hemorrhagic smallpox. The effusion of blood under the skin and the bleeding from the mucous

membranes, together with the vomiting of blood and the occurrence of bloody diarrhœa, and all associated with urgent symptoms of collapse, were strikingly similar to those found in hemorrhagic smallpox, and the termination in death from collapse afforded an additional point of similarity. If the whole picture of smallpox were due to a specific germ, it seemed to him strange that the special lesions should undergo change at a special time. He was inclined to think that the clinical picture of smallpox was the result of an infection by the specific germ of smallpox plus a purulent infection. According to such a theory, the hemorrhagic cases of smallpox would be those showing the very marked effect of pus infection.

Dr. Sara Welt-Kakels said that the case suggested acute leukæmia, and she would like to know whether or not a blood examination had been made during life.

Dr. Charles Herrman said that it was interesting to note that the attack had apparently followed "catching cold."

Dr. Kerley, in reply to Dr. Koplik's criticism, said that he did not think if the staphylococcus found in this case had been merely a contamination that it would have been found in pure culture from so many parts of the body.

Buttermilk as an Infant Food.—Dr. Herman Schwartz read this paper. He said that he had observed such excellent results from the use of buttermilk as an infant food in foreign clinics that he had determined to bring the subject to the notice of American pediatricians. That the latter had not taken up this study was quite natural in view of the strong tendency at the present time to approach as nearly as possible to mother's milk. The composition of this buttermilk food was: albumin, 34 per cent.; fat, 0.5 per cent.; carbohydrates, 10.3 per cent.; actual acidity, 0.3 per cent. or more of lactic acid. This high acidity had been found to retard the development of microorganisms. The buttermilk was found to be beneficial in fermentative diarrhœas, and no starch had been found in the fæces, except in the stools of infants under two months old. The loss of heat from the low percentage of fats was compensated for by the high percentage of carbohydrates. A good way of making the buttermilk was to centrifuge it as soon as it was delivered, in order to obtain the cream. It was then infected with lactic acid bacilli and kept in a warm room for eighteen hours before churning. In preparing the food for the infant, to a liter of buttermilk should be added 15 to 20 grm. of wheat, rice, or prepared flour, and 35 to 55 grm. of cane sugar. The mixture should be boiled for five minutes, stirring constantly. It should then be strained through a sterilized cloth and kept in sterilized bottles in the ice-chest until wanted. Curiously enough some of the children taking this food had a slight rise of temperature on beginning this diet, but it had rarely lasted for more than a day or two, and was of no significance. The stools of the children were neutral or slightly alkaline, and were homogeneous and pasty. Such stools contained very few proteolytic bacteria. Buttermilk, the speaker said, was very useful in cases in which the stools were watery and foul-smelling. In cases of fatty diarrhœa it acted extremely well. In acute intestinal disorders it was an excellent food when the acute stage had passed; in chronic intestinal disturbances it was particularly useful, and the results from its use were often surprising. The buttermilk could be used in conjunction with the malt foods. As an infant food, buttermilk was well borne by very many children. It was worthy of note that the casein of the buttermilk formed very fine flocculi, and hence was acceptable to the stomach.

Dr. Henry Koplik said that this paper showed very well how unsettled was the whole subject of infant feeding. He had seen this use of buttermilk while abroad, but while studying the method in Finkelstein's institution he had been impressed with the notion that the indications for this diet had not yet been determined by those using it there. It should be remembered that a great many infants were disturbed by an excess of fats, and the small percentage of the latter in buttermilk would explain the good effect of this diet in such children. The high acidity certainly seemed beneficial in the cases of mycotic diarrhœa which he had treated with the buttermilk food. The latter must be carefully prepared, and it was difficult at present to obtain here a good preparation of buttermilk. It should not, therefore, be condemned until it had been prepared after the manner of those using it abroad.

Dr. C. Herrman said that the fact that it had been employed for so many years in Holland showed pretty conclusively that buttermilk, as an infant food, had more than a theoretical value. The buttermilk found in this market was prepared in a variety of ways, so that it was anything but a constant article. He had found that all children would not take it, and that many parents were averse to giving it a trial.

Dr. H. W. Berg said that he understood that the buttermilk used was made from sour cream. If this practice were followed in this country the food would prove to be very costly instead of cheap, as had been claimed. Moreover, the preparation of the buttermilk food was rather complicated for ordinary domestic use. The carbohydrate in buttermilk was lactic acid, and although not claiming to be a physiological chemist, he could not but feel that if one desired to make a baby fat it would not be desirable to administer lactic acid.

Dr. S. Welt-Kakels said that she had seen the buttermilk used in the foreign clinics, and the chief indications appeared to be gastroenteritis and malnutrition. What she had observed there had impressed her favorably, and if the right kind of buttermilk could be procured here she would be in favor of using it during the summer especially.

An Unphysiological Food.—Dr. J. E. Winters said that he felt quite incompetent to discuss any method which was so unphysiological, and yet as the subject had been presented to the Section on Pediatrics it should be discussed. The first object of the practising physician should be to consult nature, and when the physician at the bedside departed from nature he erred. If there were any physiological basis for the buttermilk feeding, then, indeed, must nature have made a grievous mistake in providing 4 per cent. of fat in human milk. It was a very significant fact that all the babies treated with the buttermilk had previously been made ill by physicians who had ignored physiology, and had improperly fed these infants until they had become ill. It was not at all remarkable, therefore, that in the cases reported there should have been a temporary improvement in nutrition, simply as a result of stopping the improper food and giving the infants better care. Any physician in this city who wished to retain his family practice should be careful about going to an intelligent family and recommending the feeding of infants on sour milk, flour, and cane sugar. With regard to indigestion in infants from fats, he would say that false deductions had been made from observations upon mixtures of cream and milk. No baby could be successfully fed on a mixture of cream and milk; it must be cream only, properly diluted. If one would take the trouble to mix cream with milk one would observe that the cream very quickly separated again.

Dr. Henry Dwight Chapin said he thought the last criticism was too severe, for, apparently, the reader of the paper had not brought forward the buttermilk food as a universal food, and it should be remembered that even the most scientific infant feeding did not invariably yield satisfactory results. If we strictly observed the dictum, "Follow nature," we must never put cow's milk into an infant's stomach. He thought it probable that in a few selected cases, as, for example, cases of indigestion from the use of cow's milk, no matter how prepared, buttermilk might prove useful, and the reason was prob-

ably to be found in the fine breaking up of the nucleo-albumin which resulted from the presence of so large a percentage of lactic acid in the buttermilk.

An Experience with Buttermilk Feeding.—Dr. L. E. La Fetra said that he had tried the buttermilk food last summer in some cases of indigestion in the Nursery and Child's Hospital after the unsuccessful use of the ordinary methods of milk modification. The first obstacle met with was the difficulty of securing proper buttermilk. By boiling the buttermilk with flour the small curds visible to the eye became broken up, leaving a smooth fluid. The greatest difficulty encountered was to find a child who seemed to do well upon the buttermilk food, although care was taken to select cases in which such a diet appeared to be indicated. However, he was free to confess that buttermilk feeding seemed to him logical, for it was well known that for a long time lactic acid had been found beneficial in certain cases of diarrhœa.

Dr. Schwarz closed the discussion. He said that most of the physicians who had actually observed the results of buttermilk feeding abroad admitted that it was certainly beneficial in particular cases. He had not advocated buttermilk as a panacea for infantile ailments, yet he believed it should be useful in some cases, and, according to his experience, it had proved beneficial. It had been shown that a certain amount of carbohydrate could go to form tissue elements. He had seen children do splendidly when fed for four or five months on the buttermilk food. The German physicians had only been trying this method of feeding for a year or two, but the Dutch physicians had employed it for a great many years, and had followed individuals from birth to puberty without observing anything but good results from the buttermilk food. This method of feeding, moreover, had for a scientific basis some carefully made metabolism experiments.

NEW YORK PATHOLOGICAL SOCIETY.

Anniversary Meeting, Held January 14, 1903.

A Case of Bothriocephalus, with Remarks on the Occurrence of Bothriocephalus in America.—Dr. W. N. Berkeley presented specimens from a case of bothriocephalus. The patient was a native of Russia, forty-six years of age, a female, married, and had several children. She came to this country a few years ago. She had been passing segments of the worm for eight years, but had never had medical advice. She was in good health, had no anæmia, and complained only of vague digestive complaints. Treatment was begun, and two days later she brought the worm with the head complete to the dispensary. Dr. Berkeley said that he had been able to find no references in the literature to any cases originating in the United States. Ritchie, in his recent article on "Parasites" (*Encyclopedia Medica*), said that the worm was "seldom seen in England," but made no mention of cases in this country. Dock had observed three cases in this country, one in Colorado and two in Texas, both of which, he was satisfied, were imported. Osler also noted that there were no endemic cases. In the last edition of Braun's *Thierische Parasiten* the name had been restored to its older form, "Dibothriocephalus." Braun could mention only a single case from the United States, not stating whether this was believed to be endemic or imported. Dr. Berkeley had observed three other cases in the last four years, all in the same class of Russian immigrants. In these cases there were no signs of anæmia, and the patients complained only of indefinite digestive disorders. The parents of one patient, a small girl, claimed that she had never passed segments of worm until three months before consulting the doctor and years after her arrival in this country. On examination it was decided, however, that this was probably not correct, and the case was classified as an imported one.

Dr. Theodore C. Janeway said that he had seen a case of bothriocephalus during the week in a woman from Finland. She was in good health; hæmoglobin was 80 per cent. Her symptoms were similar to those of Dr. Berkeley's case. She had noticed passing the first segments of the worm eight years before, but said she had not seen them again until recently. The worm obtained was twenty-four feet in length.

Dr. James Ewing said that some years ago he had presented to the society three large specimens, all taken from the same subject, a Swede, who claimed not to have eaten raw fish for seventeen years. He had been entirely well and had had no signs of anæmia.

On the Nature and Origin of Blood-plates.—Dr. L. B. Goldhorn presented photographs and read a short paper on some observations which he had made on the formation of blood-platelets. After reviewing the literature, especially the work of Deetjen, Dr. Goldhorn said that the reason that there were so many varying opinions on the numbers of the blood-platelets in the blood was that in ordinary methods by heat fixation they were not well stained. Only in preparation in which very little heat was used or in which the fixation was chemical were the blood-plates present in large numbers. They were more noticeable the stronger the dye which was used, and were especially well demonstrated by the chromatin stain mixtures with eosin and methylene blue. One of the essentials was thin smears. With chromatin stains the central body could often be distinguished of a bright red color, sometimes compact, sometimes granular, surrounded by a clear zone, always capable of being stained by basic dyes. Three forms of platelets could be distinguished; one devoid of chromatin granules; one with scattered granules; and one showing many granules. In certain diseases abnormally large platelets were seen, especially in malaria. It appeared that they could undergo degenerative changes. The platelets were regularly found in the blood in intimate relationship with the fibrin; where there was no fibrin, there were no platelets. His conclusions were that the platelets were distinct and independent elements of the blood; they were not of a degenerative nature; there were several distinct types, all circular except for the occasional fusiform variety. The size varied in health and disease. As to the origin of the platelets, the speaker said that he had never had any evidence that they were derived from erythrocytes.

Dr. Ewing said that he had followed the discussion of the origin of blood-plates for a number of years and had come to conclusions contrary in certain respects to those of Dr. Goldhorn. He had found that there was very convincing evidence to show that the blood-plates originated from red blood cells and were sometimes stainable within them. He thought that there was abundant reason to believe that the platelets resulted from the extrusion of a nuclear substance from the red cells. By far the weight of evidence was in accord with this view. He thought that Dr. Goldhorn had brought out some very important facts. It seemed possible that there was more than one variety of blood-plates in human blood, and Dr. Goldhorn's minute descriptions of their morphology were an important contribution favoring this view. He, himself, had been entirely unable to distinguish in human blood more than one variety.

Demonstration of the Hæmosiderin Reaction in Corneal Vaccine Bodies.—Dr. James Ewing said that about six months before he had had occasion to bring together some evidence regarding the nature of vaccine bodies. This evidence pointed to the view that red blood cells sometimes assumed the position and exhibited the staining qualities of vaccine bodies. He had not claimed that all vaccine bodies were of this nature, nor did he wish to go so far yet. He merely wished to present some evidence which he had obtained in favor of this theory. The hæmosiderin reaction he had not been able to get in every instance; in fact, in the majority of cases the stain had been a failure, and in some sections he had succeeded in

getting the blue stain in only a portion of the vaccine bodies. The specimens were hardened in bichloride, saturated in .6 per cent. salt solution, cut in paraffin and allowed to remain twenty-four hours in potassium ferrocyanide, and six hours in hydrochloric acid. The blue color was seen only in the center of the vaccine body, and by staining with eosin or safranin the outer portion of the body took on a red stain. In many sections of human tissues the vaccine bodies gave only a faint diffuse reaction. The meaning of the blue stain thus obtained in the center of the vaccine bodies he was unprepared to discuss. He thought some would regard it as evidence that these bodies contained free iron and were derivatives of red cells. Of course, the fact that the stain was not obtained in every instance was a suspicious circumstance.

Limits of a Specific Reaction in the Serum Test for Blood.—Dr. James Ewing presented tables showing the results of experiments, conducted with Dr. Israel Strauss, relating to the limits of a specific reaction in the serum test for blood; that is, the test by which it was believed to be possible to distinguish between all varieties of blood. He said it was already known that reactions among so-called specific antisera were only quantitative and not strictly specific. The specific antibody developed in the serum of the rabbit treated with human blood would produce a reaction in a variety of other bloods as well as in human blood. Only at a certain point of dilution did the heterologous bloods drop out, leaving the reaction only in the human blood. It was therefore very necessary to determine the solutions of blood with which one worked in order to estimate results correctly. One series of experiments were made on the effects of the serum of a rabbit, which had received multiple injections of beef blood, on various other bloods. The bloods tested were human, goat, cat, chicken, sheep, horse, and beef. Various dilutions were used, from 1–10 to 1–1500. When the serum was added to all these different bloods in a dilution of one part of serum to five parts of blood, practically the same results were obtained in all. At the end of thirty minutes there was a flocculent precipitate in human blood; the reactions in beef and goat blood were more distinct than in the other, and it was not possible to distinguish the beef blood. In a dilution of serum of one to ten, human blood gave little reaction; chicken, horse, and rabbit bloods gave no reaction at all. The beef and goat were about the same. At one to fifteen, human blood dropped out entirely. The sheep still reacted. In the lower dilutions it had been about the same as the goat. Comparison of the beef and goat at one to fifteen showed rather in favor of the goat. At one to twenty, sheep blood still gave a distinct reaction, being turbid at the end of three hours. The beef gave a flocculent precipitate. At one to thirty, the sheep blood dropped out; beef and goat blood each gave a prominent turbidity about equally strong. At one to fifty, the beef blood reacted as strongly as ever, but the goat blood had dropped out almost entirely. This showed that the reaction was specific only in high dilutions. In order to get a specific reaction with the beef-rabbit serum, it was necessary to dilute the serum up to one to fifty. The dilution of the serum added seemed to be more important than the dilution of the blood to be tested. Experiments were then made with humanized rabbit serum. Two sera were tested, one prepared by Dr. Strauss, and one by Dr. Paine. With Dr. Strauss's serum tests were first made at a dilution of one to five. There was no reaction with dog, cat, or horse serum. There was a slight reaction in sheep, beef, and goat bloods. The reaction in human blood, however, was not sufficiently distinct. At one to ten goat blood dropped out. The sheep blood still reacted, but in diminished intensity. Human blood was the same. The beef reaction was slightly diminished. At one to twenty, there was nothing left but the very prominent reaction in human blood. This seemed to be encouraging for the specificity of the test for human blood until the other serum was tested, when different results were found. With this serum at one to five, the sheep, beef, and human bloods showed good reactions. There was nothing with dog, cat, or horse. This serum was evidently stronger than the first. At one to ten, human, sheep, beef, and goat blood still showed about the same reaction. At one to twenty, the reaction in the human blood was much the more distinct, but the reaction in sheep and beef blood was still quite as distinct as some obtained in human blood with the other serum. These results showed that the dilutions of this particular serum must be made above one to twenty before one could eliminate all but human blood. Some of Dr. Ewing's conclusions were: That it was unsafe to give credence to anything except a flocculent precipitate; that the time in which this flocculent precipitate occurred was of the greatest importance. Before two hours it never occurred in his experiments in any blood except that against which the serum was prepared, if the test serum had been diluted at least one to twenty. It would seem that reliable results could not be assured unless the test serum was diluted at least one to fifty.

Dr. W. H. Park asked whether Dr. Ewing knew what the rabbit serum would have done before the injections of human blood. He considered that it was very important to know the agglutinating properties of the blood before treatment, so as to judge how much of the agglutination was due to the normal blood and how much to the influence of the human or other blood injections.

Dr. Ewing said that he realized the importance of Dr. Park's statements. This work had only been done as a beginning. At the time he had himself thought it very important to know what the animal's blood would do before the experiments were made. In the first case, weak dilutions were practically inert in all the bloods tested.

Dr. F. C. Wood asked Dr. Ewing whether the strength of the dilutions of the blood to be tested were determined with accuracy or whether they were merely roughly determined.

Dr. Ewing said that the dilutions of blood had been determined with great accuracy, as was shown by the tables. A more important point, however, was the strength of the serum.

Dr. Otto H. Schultze asked whether in tests made with humanized rabbit serum there had not been some differences which the tables shown had not brought out. Dr Ewing had said that in the various dilutions all the reactions were practically the same. Had there not been some difference in the amount of the precipitate dependent upon the strength of the dilution used?

Dr. Ewing said that the greater the dilutions of the blood the larger in most instances were the amounts of precipitates obtained.

Dr. S. J. Meltzer asked whether Dr. Ewing had followed out these tests with regard to the character of the food of the animals he experimented with. It would appear that his animals could be classified into two groups: carnivorous and herbivorous animals. It appeared to him quite plausible to assume that the proteids of the bloods of animals of the same group had among themselves a greater similarity than that between animals of different groups. It would therefore be not unreasonable to expect to find that the precipitin reactions were less specific with the blood of animals which were fed in the same manner than with the blood of animals which were fed differently.

Dr. Ewing said that he had not yet got to this point. Nuttall, he knew, had attempted to classify animals by the serum reactions. He himself did not believe that the subject was in such a position that it was possible to draw reliable conclusions of this character. Investigators were in no position to eliminate just now all the disturbing results of the peculiarities of the particular animals with which they worked. He had, with the other sera, tested the serum of a chicken immunized against rabbit blood,

which acted so peculiarly that he had thought it best not to tabulate the results.

A Study of a Bacillus Resembling the Bacillus of Shiga, from a Case of Fatal Diarrhœa, with Remarks on the Recognition of Dysentery, Typhoid, and Allied Bacilli.—Dr. Philip Hanson Hiss read a paper by Dr. F. F. Russell, U. S. A., and himself on the study of an organism which had been isolated from the gut contents of a child suffering from an attack of enterocolitis. Several reasons, he said, had led to their presenting this report, chief among them being the vital importance of establishing beyond a doubt the etiology of the various forms of diarrhœas and dysenteries, since upon such establishment must ultimately depend the rationale of hygienic, diagnostic, and therapeutic measures—especially those of serumtherapy, and diagnosis by serum reactions—upon which the recognition and cure of the disease or protection from the infective agent must be based. There was the greatest need, he said, in the present state of the knowledge of the etiology of dysentery, of the most careful study, description, and especially comparison of the bacterial forms supposed in different cases and various localities to be of etiological significance in the same or various forms of this disease. The organisms isolated from cases of dysentery—apart from a determination of superficial resemblance in growth characters on the usual nutrient media and their reactions in the presence of the more commonly employed sugars, dextrose, lactose, and saccharose—had been largely identified by their supposed agglutination reactions in the presence of serum from dysentery patients and immune animals. That there were serious objections to placing too complete confidence in such measures alone the authors thought would appear from their study. The organism was a short, fairly stout bacillus, with rounded ends, and corresponded in staining reactions and morphology to Shiga's bacillus. The organism grew well on the usual culture media and corresponded in all essential respects to Shiga's bacillus. Gelatin was not fluidified, nor was indol produced. On nutrient broth a small pellicle was formed after ten or twelve days. A study of the organism in dextrose, lactose, and saccharose bouillon in fermentation tubes showed a complete correspondence with the bacillus of Shiga; but it was to be differentiated from this organism by its ability to ferment mannit. A differentiation was obtained by the study of the organism in a medium composed of beef serum, one part, and distilled water, two parts. This medium could be boiled without causing coagulation of the albuminous bodies present. The medium after boiling was an opalescent fluid. To this was added the different sugars to be tested, and the medium was rendered distinctly blue with litmus. The sugars which had been tested were dextrose, galactose, mannit, maltose, lactose, saccharose, and dextrin. The bacillus of Shiga was found to ferment dextrose and galactose with acid formation, as was shown by the reddening and coagulation of the medium in the tubes. Mannit, maltose, lactose, saccharose, and dextrin were not fermented by this organism. The bacillus described by Dr. Hiss fermented dextrose, galactose, and mannit with acid production and reddening and coagulation of the medium. The mannit fermentation thus differentiated this culture from the true Shiga bacillus. The bacillus typhosus was found to ferment dextrose, galactose, mannit, maltose, and dextrin. The active motility of the typhoid bacillus as well as its ability to ferment maltose and dextrin differentiated it from the bacillus described. A study of the agglutinating reactions of the bacillus was made with various normal and immune sera and with the serum of an animal immunized against the bacillus itself. It appeared from these tests that this organism agglutinates with dysentery sera from human infections and from immunized animals in most instances quite as well, and in some better, than the bacillus of Shiga. A point of interest was the agglutination of the bacillus in high dilutions of sera from animals immunized against typhoid. This was not true of the Shiga bacillus. The facts brought out in regard to the serum reactions of this organism and Shiga's bacillus had an important practical bearing. Unless careful studies were made of all organisms resembling Shiga's bacillus gross errors might occur in serum diagnoses based upon the use of such organisms in testing reactions; and errors might also occur in identifying such organisms themselves by simple tests against dysentery sera. This was illustrated by the fact that this organism agglutinated better even than the Shiga bacillus in dysentery serum, and unless true Shiga bacilli were tested against its immune serum they might not be differentiated from each other. The authors thought it more than probable that organisms corresponding to theirs had been already isolated and not recognized as distinct from Shiga's bacillus. This might lead to the mistake of establishing the identity of a dysenteric or diarrhœic attack with true dysentery by agglutinations obtained by the use of a bacillus differing from the supposed etiological organism. They considered it fortunate that the study of cultural characters had aided in the recognition of differences in these organisms and might be of further service in the recognition and grouping of new organisms as they were discovered. Formerly this organism could not have been differentiated by culture tests from the bacillus of Shiga and might easily have been confounded with Shiga's organism. The bacillus described was closely related to bacillus typhosus, both in agglutinating reactions and in the usually observed cultural characters, but could be separated from it by its absence of motility and by its reactions in the maltose and dextrin media employed by us. A description of this organism, apart from its connection—which may or may not be etiological—with the case of diarrhœa, had seemed important since the tests of its ability to agglutinate, to often alone relied upon, might lead to its being confounded with Shiga's bacillus. A subsequent use of such an organism for serum diagnosis might give rise not only to confusion in determining the "specific" character of a disease, but to untoward results in the application of serumtherapy. Its etiological significance had not been established, but its close physiological connection with the dysentery bacillus on one side and the bacillus of typhoid on the other make it not improbable that further research will show it to be related etiologically to dysenteric attacks.

Dr. David Bovaird gave details of the case from which the organism described by Dr. Hiss had been isolated. The patient was a child of about one year, who suffered from an attack of enterocolitis. The temperature was not high, never over 100°. There was persistent diarrhœa, from four to six stools every day. For the most part they had been green and contained mucus. There had been no mention of any blood in the stools. The child lost strength progressively and died in two weeks. Dr. Bovaird considered that Dr. Hiss' results were of the utmost importance. He said that it was only a short time since the society had listened to Dr. Flexner describe the finding of the bacillus of Shiga in approximately fifty cases of dysentery in children, and since that occasion there had been numerous reports of the finding of the bacillus in diarrhœas of children in various parts of the country. Efforts had already been made to develop a serum which would be of use in the treatment of these cases. He had but recently read the report of the work of Gay of the University of Pennsylvania, who thought he had been able to produce such a serum. Since, therefore, it was evident that we were approaching the treatment of some of these cases by sera, it became very important that the diagnosis in all cases should be very exact before such treatment was undertaken. Such observations as Dr. Hiss's were, therefore, of great value in indicating a possible source of error. Further investigation would be required to determine the full application of

Dr. Hiss's observations. If the Shiga bacillus were found to be the specific cause of many of the diarrhœas common in children, the association with the term dysentery would be a source of some difficulty and confusion. That term had not been seen in pediatric writings for some years, and there was no clear conception of the clinical picture which it should call up. Certainly there were marked differences between the diarrhœas common in children during the summer and the condition in adults designated as dysentery. If it were consistent with the facts it would be an advantage in discussion to employ the term colitis or enterocolitis, which would be much more definite and clear.

Dr. W. H. Park said that only the night before Dr. Smith had inoculated all these different bacilli in nutrient agar to which litmus and mannit had been added. There was no question that on this medium, which had a trace of meat sugar, the Shiga bacillus and the Flexner New Haven culture stood out perfectly clearly from the rest in not having produced appreciable acid. Although the elimination of the meat sugar might be insisted on, so as to judge what effect the bacilli had on mannit, yet the marked difference between these bacilli and all the others was just as important in showing differences between the bacilli as if the medium had contained only mannit. Dr. Park did not think it correct to speak of developing in this country a new serum for dysentery. Shiga had used the serum in a number of cases, and attempts made here so far had been simply copies of what he had already done. Shiga himself had only employed the usual methods. He thought it was a mistake to go too fast in applying the results obtained by those working under Dr. Flexner at Baltimore to ordinary summer diarrhœas until it was proven whether all these bacilli were really essentially identical, and also whether it might not be true, as seemed probable, that the conditions at the Wilson Sanatorium were unusual in the amount of infection which existed with dysentery-like bacilli.

Dr. Hiss said that the tubes of Lentz's medium shown contained media made according to Lentz's formula, and also mannit media made from sugar-free infusion. If held against the light one could see that the sugar-free tubes showed no growth except at the surface and not along the line of inoculation.

Dr. E. Libman said that he thought there were several points in Dr. Hiss's paper deserving of corroboration. He had noticed, as had Dr. Hiss, that the medium described by Drigalsky and Conradi was not made sugar free, and he had, therefore, hesitated about using it. As regarded the value of agglutination reactions for the diagnosis of dysentery, he had examined a number of bloods from cases not having a history of dysentery to ascertain whether the reaction was specific; for he thought the reaction, if specific, could be used to establish the identity of certain conditions which appeared to be sequelæ of dysentery (the patients at the time of observation not having evidences of dysentery). He had examined the blood from ten cases taken at random in the wards. The reaction was absent with the Flexner bacillus in all but two cases. One case of autointoxication gave a good reaction at 1–50, and a case of rheumatism gave a good reaction at 1–100 in twenty minutes. Possibly in higher dilutions the agglutination tests might have been specific. He was interested in Dr. Hiss's remarks about the occasional absence of clump reactions in low dilutions when present in high dilutions. He had himself observed this with immune typhoid serum. This was an important point practically. He had examined the blood of two cases of typhoid fever, which had given only a slight reaction at 1–20, but a complete reaction at 1–50 and 1–100. As only complete reactions could be considered in making the diagnosis of typhoid fever, he believed that when a blood does not react in low dilutions, higher dilutions should be tried. It seemed probable from the paper just read that just, as in cases of paracolon infection, the organisms showed variations, the same was true of dysentery, and in the same the clinical picture of typhoid fever was due to a variety of organisms. Dr. Libman said he had recently seen a case of typhoid fever with perforation in which the Widal reaction was absent. Typhoid bacilli could not be found, but in the mesenteric lymph nodes, at the autopsy, the bacillus fecalis alkaligenes was found. Serum reactions could not be tried. He did not wish to draw any conclusions from this finding, but believed it was of interest because this organism had been discovered by Petruschky alone or with the typhoid bacillus in cases having the clinical picture of typhoid fever.

A Method of Separation of Colonies of Shiga's Bacillus from the Colon Bacillus.—Dr. E. K. Dunham gave an outline of studies of the influence of the physical properties of gelatin upon the appearance of colonies grown on plates. The physical characters chiefly noted were: The viscosity, the melting point, and the penetrability or spissitude. It seemed to him that a knowledge of the viscosity and the melting point was sufficient for a practical guide to the influence of the gelatin on colonies. To obtain a differentiation of colonies it was found desirable to grow them in a soft jelly, either by making a soft jelly to start with or by using a stiff jelly and incubating the plates at a high temperature. The size of the colonies was smaller if the plate was allowed to stand and harden at the room temperature before being put into the incubator, considerably larger if put at once into the incubator. In twenty-four hours the colonies prepared in the latter way were larger than colonies forty-eight hours old in a similar but softer jelly, grown at the same temperature, but chilled before incubation. In a soft jelly the typhoid bacillus formed threading colonies. The colon bacillus in a very soft jelly does not produce single colonies, but a collection of small colonies. The dysentery bacillus always produced a perfectly spherical colony, except in jelly that was so soft as to be semifluid. For practical purposes the dysentery bacillus produced a perfectly spherical colony, easily distinguished from the colon and typhoid, more difficult to distinguish from the paratyphoid. It seemed, therefore, that in plating fæces it would be very easy to ignore the colon bacillus and pay attention only to the spherical colonies. This would reduce the difficulty of finding the dysentery bacillus, and could easily be done in twenty-four hours.

On the Interpretation of Reactions of Agglutination among the Bacilli of Dysentery.—Dr. William H. Park gave the results of some experiments in agglutination reactions done by Dr. Collins and himself, in the course of which they had struck some things which he considered very remarkable. These were along the lines of Drs. Hiss's and Libman's remarks, except that they were perhaps more striking. He first spoke of normal goat serum and the necessity of knowing the serum agglutination results before the animal was inoculated. The serum from different goats varied widely. Experiments were made with the Shiga, Flexner Manila, and New Haven bacilli, and with the bacillus isolated by himself and Dr. Dunham at Seal Harbor, Mt. Desert, and also with a bacillus furnished by Dr. Wollstein from one of a series of cases of dysentery occurring in the Foundling Asylum in New York City. In normal serum from goat 3 the Shiga, Flexner Manila, and New Haven bacilli agglutinated perfectly up to 1-200 within from one to one and one-half hours, while the Seal Harbor bacillus refused absolutely to clump in any dilution above 1-10. After the goat had been inoculated with three injections of the Seal Harbor bacillus the tests showed that all the bacilli mentioned were clumped in dilutions somewhat above 1-200 except the Seal Harbor. This agglutinated in dilutions only up to 1-50. This at first seemed unexplainable until reference to the results of the normal serum tests already spoken of showed that the slight reaction of the Seal Harbor bacillus in the serum of goat 3, after moderate injections with it, was due to the fact that the goat originally had almost no agglutinating

substance for this bacillus, while having much for the others. Such experiences proved the necessity of knowing the properties of the animal's serum at the beginning, before injections of bacteria or blood were made. After five injections of Fexner's Baltimore cultures, the horse serum clumped all the bacilli except the Shiga and Flexner New Haven cultures, which did not clump at all in dilutions higher than 1-75. All the others clumped up to 1-1,000. A bacillus obtained by Dr. Park from three persons suffering from chronic dysentery, which in sugar fermentation was closely allied to the colon bacillus, clumped in this Baltimore culture horse serum in dilutions up to 1-10,000 Curiously enough, this bacillus had clumped in every dysentery serum in which the Flexner cultures other than the New Haven were clumped. In two human typhoid immune sera the Shiga and New Haven cultures did not clump at all, while the New York, Manila, and Baltimore cultures clumped in 1-50 and pretty well in 1-100. In this serum the Seal Harbor and Tuckahoe bacilli fell into the Shiga group, as did the bacillus from the chronic dysentery case. Tests with serum from a patient with a staphylococcus abscess gave no reaction with the Shiga, New Haven, or Seal Harbor cultures; but an absolute reaction in dilutions of 1-100 with the chronic dysentery, Baltimore, Wollstein, and colon bacilli. Throughout all the agglutination tests the Shiga and New Haven bacilli showed divergence from the others. They had not been agglutinated by the agglutinating substances produced by or acting upon the others. The results of the tests with the colon-like bacillus which agglutinated in dilutions of 1-10,000 in the serum of a horse immunized with Manila and Baltimore dysentery bacilli seemed to show that simple agglutinations, even in dilutions much higher than those effective upon the organism used to immunize the animals, were not enough to prove relationship between bacteria. In alkaline peptone mannit litmus nutrient agar the New Haven, Tuckahoe, and Shiga cultures did not change the blue color in twenty-four hours. In all the other cultures production of acid occurred. The Flexner Manila, Baltimore, Seal Harbor, and New York cultures produced indol in twenty-four hours in peptone water, while the Shiga and New Haven cultures did not, even in fourteen days' growth. Both in indol and acid productions, therefore, as well as in agglutination reactions, the Japan and New Haven cultures were separated from the Manila, Baltimore, New York, and Seal Harbor cultures.

Dr. Charles Norris asked by what method Dr. Park had made these agglutination reactions, and what limits he used in determining them. The results seemed to him very extraordinary. Had Dr. Park used the microscopic method? He had himself got hold of a highly immune serum, but had never been able to obtain higher agglutination reactions than 1-100 or 1-150. By the microscopic method he had got reactions up to 1-300. He had been particularly surprised by Dr. Flexner's remarks that he had got agglutinations in dysentery cases up to 1-1,000. He had never been able to obtain any nearly so high. The thing might depend upon what one called an agglutination reaction.

Dr. Park said that with the goat serum the complete reactions were both in the test tube and hanging drop. The dilutions of the immunized horse serum were mostly tested by the hanging-drop methods. Up to three or four hours the results obtained with the two methods were identical. For longer times the tube method gave the more accurate results. All the results were obtained within two or three hours, when the hanging drop was used, most of them within two hours. The complete precipitation of the bacilli in the tubes when agglutination took place was slow, requiring a number of hours. The cultures used were broth cultures, three to six hours old. Equal parts of the diluted serum and of the broth cultures were mixed together.

Dr. E. Libman asked whether Dr. Park had found any thread reactions. In his own experience, under certain conditions, the same organism, after it had been grown for a length of time in various media, would often change, as regarded its reaction. He had observed a paracolon bacillus which, at first, gave only a thread reaction with the patient's blood, and not with any other blood, but which, after a time, gave a clump reaction with almost any blood tried against it. He asked whether Dr. Park had tried the reactions against any large number of normal sera.

Dr. Park said that in testing blood sera from patients in dilutions of 1-10 to 1-50, he had found a great many thread reactions after twelve to eighteen hours. In high dilutions with the sera of immunized animals he had seldom found any.

Dr. P. H. Hiss said that in connection with Dr. Park's remarks he was reminded of Shiga's latest article, in which Shiga described the growth of his own bacilli in milk, by which means he got precisely the same reaction with the true Shiga bacillus as with the Flexner bacillus. Dr. Hiss said that the results of his serum tests did not seem to show a correspondence between the Flexner bacillus which he had tested and the organism "Y" which he had described. The "Y" had the power of agglutinating in very high dilutions, whereas the Flexner tested by him always agglutinated much less readily in dysentery sera, and in other sera against which it was tested. He also said that the results of serum tests, both in America and Europe, indicated to him that one at least of Flexner's organisms did not react as did the Flexner organism tested by Dr. Park—that usually it showed a markedly less agglutination than "Kruse," "Shiga," and "New Haven" in dysentery sera, from animals not immunized against itself.

Dr. Park said that he thought Dr. Hiss had misunderstood Shiga's article. He had had the same idea after first reading it, but after a careful re-reading, it became plain that Shiga said that the pro-agglutinoid zone was changed by the growth in milk, but not the agglutinating reactions. The Shiga bacillus still failed to remove the substances agglutinating the Flexner Manila culture, and *vice versa*.

Dr. S. J. Meltzer and Dr. Clara Meltzer gave a demonstration of the action of adrenalin injected subcutaneously on the vessels of a rabbit's ear, after section of the nerves.

Dr. Smiles.—Dr. Smiles, the author of "Self Help," who celebrated the completion of his ninetieth year the other day, was a doctor "by first intention." He was born at Haddington in 1812, and educated at Edinburgh, becoming in due course a licentiate of the Royal College of Surgeons of that city. He practised as a doctor in Haddingtonshire for six years, but his tastes lay in another direction. His opportunity came to him earlier than to most men. He was offered the editorship of the Leeds' *Times*, and from the drudgery of editorship he rose to be Secretary of the Leeds and Thirks Railway, and afterward of the South-Eastern. He is best known, however, by his books. In addition to "Self Help" he has produced "Lives of George and Robert Stephenson"; "Lives of the Engineers"; A Life of John Murray"; "Thomas Edward, Scotch Naturalist"; "Robert Dick, Geologist and Botanist"; and a series of works of a homiletic character—Duty, Thrift, Character, Conduct, etc. The publisher to whom Dr. Smiles first offered "Self Help," when the Crimean war was raging, would not look at it. "People won't read anything of this kind," he said. After the book had lain for years on his desk, Dr. Smiles published it at his own expense. It at once became popular. Twenty thousand copies were sold in the first year, and since then its circulation has gone beyond the quarter million mark.—*British Medical Journal.*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending February 21, 1903:

	Cases.	Deaths.
Measles	190	7
Diphtheria and croup	386	45
Scarlet fever	262	19
Smallpox	3	..
Varicella	103	..
Tuberculosis	318	195
Typhoid fever	48	9
Cerebrospinal meningitis	..	..

Nomenclature of Malaria.—(1) It would seem that the time has arrived when the diagnosis of cases of malaria must aim at giving the name of the species or variety dealt with, and not merely one of the general terms—intermittent or remittent fever—as laid down in the last edition of the *Nomenclature of Diseases*. (2) Information is wanted as to the geographical distribution of the various kinds of malaria, and this can only be arrived at by recognizing them in the new edition of the *Nomenclature*. (3) The demonstration of the species of malarial parasite which is the infecting agent in a particular case will necessitate the use of the microscope. This routine microscopical examination of the blood will, it may be presumed, bring about a more correct diagnosis of fevers in malarious countries, and assist toward rational treatment. Malta fever was treated until lately with large doses of quinine, on the supposition that it was malarial in origin. In the same way it is too often assumed that any fever occurring in a malarious locality is malarial in character, and quinine is given in enteric fever, tuberculosis, liver abscess, etc., when a blood examination might have prevented the error. (4) The nomenclature I would suggest for the three well-recognized species of malaria is the following: Malarial Fever: Synonyms—Ague, intermittent and remittent fevers (*a*) Tertian synonyms—Hæmamœba vivax, simple or benign tertian; (*b*) Quartan synonyms—Hæmamœba golgii; (*c*) Crescent tertian synonyms—Laverania laverani, estivo-autumnal fever, malignant tertian, tropical tertian, remittent fever. I have left out the commonly used terms, simple, benign, malignant, pernicious, as they are misleading. The so-called simple tertian may often be more severe than the so-called malignant tertian. Estivo-autumnal is a term which may be applied appropriately enough to the fever as it occurs in Italy, but in other parts of the world it is also misleading. In regard to the scientific names, I think Golgi, who discovered that the parasite consisted of more than one species, should be commemorated, and also Laveran, whose epoch-making discovery of the malarial parasite has, it seems to me, never been sufficiently appreciated.—Lieut.-Colonel David Bruce, R.A.M.C., in *British Medical Journal*.

Odd Tea-drinking.—When the natives of Paraguay drink tea they do not pour it from a tea-pot into a cup, but fill a goblet made out of a pumpkin or gourd, and then suck up the hot liquid through a long reed. Moreover, the tea which they use is altogether different from that which comes from China, being made out of the dried and roasted leaves of a palm-like plant which grows in Paraguay and Southern Brazil. The natives say that this tea is an excellent remedy for fever and rheumatism, and chemical tests which have been made by German physicians seem to show that there is good ground for this statement. Certain it is that tea is widely used throughout Paraguay in cases of illness, and that, so far as has been observed, the effects produced by it are highly beneficial.—*New York Herald*.

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ending February 21, 1903:

SMALLPOX—UNITED STATES.

RADIO-PRAXIS.*

By HENRY G. PIFFARD, M.D., LL.D.,
NEW YORK.
PROFESSOR (EMERITUS) OF DERMATOLOGY, NEW YORK UNIVERSITY.

"Science ought to teach us to see the invisible as well as the visible in nature; to picture in our mind's eye those operations that entirely elude the eye of the body."—TYNDALL.

MANY years ago, probably twenty-five, the writer employed sunlight, concentrated by means of a glass lens, in the treatment of a few cases of lupus, and other semi-malignant lesions of the skin. In these instances the active rays comprised those belonging to the visible spectrum, together, of course, with such of the invisible rays as were capable of traversing the lens. While glass is exceedingly transparent to the visible rays from red to violet, it has long been known to present a serious obstacle to the passage of the invisible rays beyond the red. More recently it has been learned that it is an almost impossible barrier to some of the rays that fall below the other end of the visible spectrum, the ultra-violet rays as they are called. These rays cannot be assigned to any definite wave-length, but may be approximately grouped about a wave-length of, say, 0.25 of a micron.

The red light waves are largely accompanied by heat waves, but still the other light waves, even to violet, possess some caloric properties, as was first ascertained by the late Prof. John W. Draper.

In the writer's applications, therefore, the waves emanating from the entire spectrum were employed, but the most noticeable effects were clearly those due to the heat rays. In other words, the lesions were simply burned out. As there were other simpler and more convenient methods of burning, the sunlight burn was discarded for that of the galvano-cautery. The use of the solar-cautery, however, has been recently revived in Italy.[1]

A few years since, Finsen of Copenhagen again took up the question of utilizing the sun's rays in the treatment of superficial malignant affections, but instead of depending on the caustic rays as I had done, sought to exclude them, and to employ the so-called chemical or actinic rays, namely, visible rays of short wave length, and the invisible ones of still shorter. In this he was measurably successful, using the customary ammonio-sulphate of copper solution as a ray-filter, and to absorb the heat.

That the original Finsen method was effective in many cases of malignant diseases admits of no doubt, but its practical use was accompanied with serious inconveniences, namely, the length of the individual exposures (an hour or more), their necessary frequency (in many cases daily), and the great cost of the installation and maintenance.

It was altogether probable, however, that the chief efficacy of the treatment was due to the ultra-violet rays, and Finsen decidedly increased the efficiency of his apparatus by substituting the electric arc for sunlight, and quartz for glass as the medium through which the rays are transmitted. This materially shortened the length of the necessary exposures.

It was, of course, to be expected that others would seek to improve on Finsen's apparatus, both as to cost of installation and maintenance, and efficiency in action. The Lortet-Genoud and the Bang Lamps[2] were constructed to accomplish these ends. With these lamps the time of exposure, it is stated, has been materially decreased.

Of all the low tension arc lamps that I have seen or heard of, a recent French model appears to me as being the most practical. It has twin arcs connected in series, and so arranged that the light from both is projected to the same point.

By connecting these arcs in series we obtain nearly double the effect at the same expenditure for current, as with a given amperage and voltage we are thus utilizing twice as much of the available electric energy as if we used a single arc, and wasted an equivalent amount of energy in uselessly heating the rheostat.

It has long been known that the light from the ordinary electric arc is accompanied with a much larger proportion of ultra-violet radiations than sunlight, but Görl[3] of Erlangen has availed himself of the fact that the condenser spark is still more richly endowed with these rays, and has devised a lamp for their utilization, a point to which I will again refer.

The wonderful discovery of Röntgen that certain radiations would readily traverse many bodies that are absolutely opaque to luminous rays, naturally led to an investigation of their influence on the human tissues on which they might impinge, and it was soon learned that undue exposure to these rays led to more or less injury, and, in fact, destruction of the tissues subjected to their influence. From this it was but a step to an experimental research into their therapeutic uses, and it was found that they could be used to advantage in many of the cases in which the ultra-violet rays had already been found useful by Finsen and others, namely, superficial lesions of a more or less malignant character. That there was a notable difference between them, however, was early apparent, as in many of their physical manifestations their behavior was totally unlike.

If we assume the truth of the wave theory of light, we may assert with extreme probability that the ultra-violet rays are etheric vibrations with wave-lengths approximating 0.25 μ. On the other hand, there is but little if any evidence that the x-rays have any relation whatever to etheric vibrations, or if, perchance they do, there is absolutely no clue to their wave-length. In fact their very name x, used in its algebraic sense, indicates how little we really know about them.

If we compare the Röntgen rays with the ultra-violet radiations we will note some resemblances,

*Read before the New York Academy of Medicine, February 19, 1903.

but still some notable differences in their physical manifestations:

X-Rays.	Ultra-violet Rays.
1. Cannot be reflected refracted, or polarized.	1. Can be reflected, refracted, and polarized.
2. Can penetrate and traverse many bodies that will not permit the passage of luminous rays: *e. g.* wood, aluminum, etc.	2. Will not traverse many bodies that are perfectly pervious to luminous rays, *e. g.* glass.
3. Will readily traverse the superficial tissues and influence the nutrition of the deeper ones.	3. Will not influence the deeper tissues, nor even the superficial ones, unless they are deprived of their usual blood content; that is, dehæmatized.
4. Will traverse a thick book.	4. Will be stopped by a single leaf of the same book.
5. Have no appreciable effect on the vitality of bacteria.	5. Will rapidly destroy the vitality of bacteria.
6. Will discharge an electroscope either positively or negatively electrified.	6. Will discharge an electroscope if electrified negatively, but not positively.
7. Will excite bright green fluorescence in Willemite, and induce *white* phosphorescence in polysulphide of calcium.	7. Will excite bright green fluorescence in Willemite, and induce *blue* phosphorescence in polysulphide of calcium.
8. Rock salt is *opaque* to *x*-rays.	8. Rock salt is *transparent* to ultra-violet rays.

The differences here pointed out indicate the fact that we are dealing with agents of totally dissimilar nature, although in certain forms of disease they may both be used to effect the same end; that is, the treatment of cutaneous affections of an extremely superficial character, while *x*-rays may further be used for the successful treatment of deeper lesions.

So much has been recently published concerning the therapeutic uses of the *x*-rays that I will leave them from present consideration, and turn more particularly to the later developments in actinic therapeutics, referring the reader more particularly to a paper by Walsham,[4] and a recent work by Turner.[5]

As already stated, Finsen's original installation has been supplanted by modified forms of apparatus, in part devised by Finsen himself and in part by others.

Of those employing the usual low potential arc, the lamps of Bang and of Lortet-Genoud are the ones that have received the most notice. In the Bang lamp the terminals are of iron instead of carbon.

The Lortet-Genoud, slightly modified, is known in London as the "London Hospital Lamp." It has the arc so arranged that it can be brought into close proximity to the affected part, and has a special cooling device and a quartz compressor.

The Görl lamp differs radically, both in principle and in construction, from the Finsen and the other lamps that have been mentioned. Instead of using the commercial low tension current with carbon or iron terminals, he employs an extremely high tension, high frequency current obtained from an inductorium or *x*-ray coil in connection with a condenser and metallic (aluminum) terminals.

He chose aluminum under the supposition that the passing spark would be richer in ultra-violet rays than if the terminals were of carbon, as in the Finsen arrangement for low-tension current.

This lamp, somewhat modified by the substitution of iron terminals and in some other points of detail, has been specially experimented with in London, where it is known as "St. Bartholomew's Hospital Induction Coil Arc Lamp."

With the Görl or St. Bartholomew's lamp, as employed abroad, a compressor, to render the part bloodless, is employed in the same manner and for the same purpose as in the later low-tension outfits, quartz, rock-salt or ice being used. This lamp being comparatively new has, of course, not been used to anything like the extent that the Finsen and its modifications have, but the results obtained appear to have been equally as good as with the low-tension arc or the Röntgen ray, and have been secured more promptly, and with vastly less inconvenience to the patients.

It must be understood, however, that the Finsen and the Görl appliances are adapted to superficial lesions only, while the Röntgen ray is capable of directly influencing the deeper structures. There is one notable difference, however, between the action of the Röntgen and the ultra-violet rays. This relates to the inflammatory and congestive reactions. With the latter the reaction appears promptly and disappears rapidly, and with no permanent ill effects other than a possible tanning of the skin. With the former the reaction is tardy, disappears slowly, and sometimes results in very serious ulcerations.

The chief difference between the original Görl lamp and the London imitation lies in the fact that the former has four spark gaps, while the latter has but one. The advantage, it appears, rests with the original. I have obtained one of the London lamps and am not disposed to speak favorably of it, as regards either design or mechanical construction, and I give decided preference to a modified Görl lamp that has been made for me here by the Waite & Bartlett Mfg. Co. It has three spark gaps, and is much more efficient than the London lamp.

A very convenient and accurate method of testing the comparative efficiency of two or more of these lamps, is to connect them in series with each other and with the electric source. In this way each lamp receives exactly the same amount of current. If we now arrange them face down on a piece of sensitized paper (preferably solio), and turn on the current for, say, a couple of minutes, we will be able at the end of that time to perceive readily the effect each lamp has produced. This effect, however, is not wholly due to ultra-violet rays, but is in part due to the chemical B-V rays. In order to ascertain the part that each set of rays plays in darkening the paper, we may take a fresh piece and interpose a thin piece of glass between the lamp and the paper. Let the current pass for two or three minutes, and then quickly shift the lamp to a fresh piece of the paper and expose for the same time without the intervention of the glass. This experiment exhibits, in a very striking manner, the vastly superior efficiency of the ultra-violet rays over the blue-violet elements of the spectrum.

As already stated, the ultra-violet rays will not traverse blood or tissues in which blood is circulating, and it is necessary, therefore, to dehæmatize the tissues, and the only practical method so far proposed is by means of a compressor with which to mechanically squeeze the blood out of the parts. This compressor must, of course, be permeable to the rays, and quartz, therefore, is the material commonly employed. In some lamps this compressor is lenticular, in others simply a plane quartz plate of circular form. To obtain any benefit, therefore, from the apparatus, firm pressure must be made on the part. This is tiresome, to say the least, but in most cases may be left in the hands of the patient himself, with the assurance that the harder he presses the greater will be the effect. With the newer devices, whether employing the low or the high-tension arc the seance rarely exceeds ten or fifteen minutes, and may be repeated daily.

If any reaction results, it will probably subside if the use of the rays be discontinued for a few days.

The most annoying part of the procedure is the maintenance of the compression, and yet there is an exceedingly simple means of dispensing with it altogether, namely, by the use of suprarenal extract. If the lesion be open and ulcerated, a little of the extract, preferably in the form of adrenalin chloride, applied directly to the part promptly bleaches it and permits the ultra-violet rays to act. If the lesion, however, be still covered by epithelium, the adrenalin may be injected either pure or diluted with a deci-normal salt solution. This same idea appears to have occurred independently to Jamieson, who says:[6]

"When adrenalin in the 1-1000 solution is closely applied for ten or fifteen minutes to such a patch, by means of a piece of absorbent cotton moistened with it, the effect produced is a distinct paling of the skin around the lupus spot. Strange to say, no great diminution of redness occurs in the lupus area itself, which is still quite conspicuous in the center of the whitened area; yet the effect produced by light is certainly greater than when adrenalin has not been used."[6]

I have found, however, that altogether the most satisfactory method of using suprarenal extract is in the form of a solution of adrenalin chloride, introducing it by cataphoresis. The cataphoric electrode, covered with a thickness of lintine, or similar material saturated with adrenalin, is connected with the positive pole of the battery, or other electric source. It should then be applied to the part that we desire to dehæmatize, using a current of about 3 or 4 m.a. If the electrode is maintained in contact with the part for four or five minutes, it will thoroughly bleach it, and make it ready for the application of the ultra-violet rays.

The quartz compressor may still be used, but without compression, but simply to protect the part from bulging up too near the spark-gaps, that is, when using the high-tension arc. When using the low-tension arc, which is usually some inches from the affected part, this protection is unnecessary.

So far as I am aware, the condenser-spark lamp has been used by others only in connection with a coil as practised by Görl and in London. Personally, I use the static machine as the source of high-tension electricity, and as condenser use Leyden jars having about 100 square inches of internal, and the same area of external foil surface in connection with each pole of the machine. The lamp is then connected by its conducting cords to the outer surface of the jars. The poles of the machine when in action are separated about one inch, but the spark-gap between the terminals of the lamp is only about one-eighth of that distance. The minute size of this spark, as compared with that of the ordinary low-tension arc, might lead us to doubt its possible efficacy, but the clinical experiences thus far reported seem to justify the belief that in this spark we possess a very valuable therapeutic resource, and every probability points to the ultra-violet rays as being the active agent. Finsen at an early day arranged his low-tension arc so that two or more patients could be treated simultaneously, but in the lamps recently devised this is not practicable. With the high-tension arc, however, whether actuated by coil or static machine, two or three, or for that matter a dozen, lamps may be connected in series, and may be used to treat an equal number of patients simultaneously.

Insomuch as the ultra-violet rays are invisible, it may be asked how we determine their presence. In other words, is there any convenient test by means of which their existence or absence may be readily ascertained. One test mentioned by many writers is that performed with the aid of the electroscope. If a goldleaf electroscope be charged with negative electricity, the ultra-violet rays will discharge it; but if charged positively, they do not affect it. The most convenient test, however, for the presence of the ultra-violet rays, that is known to me, is by means of the mineral Willemite; this is a silicate of zinc ($ZnSiO_4$), and when exposed to the ultra-violet rays exhibits a beautiful greenish fluorescense. If, however, a thin piece of glass, as an ordinary spectacle lens, be interposed between the rays and the mineral, the fluorescence instantly disappears, showing, as already stated, that the rays do not traverse this medium. If, however, a thin quartz plate be substituted for the glass, the fluorescense again becomes apparent.

If we now exposed a piece of Willemite to the *x*-rays it will fluoresce as before, but the fluorescence will persist even if glass be interposed.

Another silicate of zinc (H_2ZnSiO_5), the mineral calamine, does not fluoresce when exposed to either the ultra-violet or the *x*-rays.

Nearly two years and a half ago[7] I called attention to the use of an up-step transformer in connection with the static machine, whereby the static induced current was passed through the coil of coarse wire and induced a current of higher potential in the secondary coil. An electrode was connected with one of the terminals of this latter coil and brought near the cutaneous surface that I desired to influence. When near enough (one or two centimeters), a spark jumped from the electrode and impinged on the skin. The electric current then traversed the body, seeking the most convenient path to earth. To this spark I later gave the name "hyperstatic," to imply that the potential of the static current had been raised, and to the instrument the term "hyperstatic transformer" has been applied. The results obtained by the use of this spark in a variety of cutaneous lesions were surprising, surpassing by far those obtainable by the usual dermatological applications. As noted in my previous paper, the application of the sparks, which are not very painful, for a period of four or five minutes, results in a prompt hyperæmia, which usually subsides in a day or two. If we are, for instance, dealing with an infiltrated eczema, the infiltration subsides *pari passu* with the induced reaction, and a complete disappearance usually follows a very limited number of applications.

In my early experiences I attributed the reaction to the electric bombardment, and the ultimate results to the same agencies that are involved when we apply an ordinary cutaneous irritant. When, however, I became cognizant of the effects of the ultra-violet rays from the condenser spark it seemed probable that we had not only these but much more besides. To test the matter, I darkened the room and held a piece of Willemite near the spark. It immediately fluoresced. If the electrode be now withdrawn a little beyond the sparking distance, a spray of violet light will be observed, accompanied with ultra-violet radiations, as made manifest by the fluorescence. If we analyze the phenomena connected with the hyperstatic spark, we find we have (1) electric bombardment of the tissues, with probably ionization; (2) projection of metallic particles from the electrode (if of metal); (3) ultra-violet rays; (4) dissociation of the oxygen atoms, and their rearrangement as ozone; (5) destruction of bacteria.

I was by no means the first to adopt an up-step

transformer to a high-frequency current, as Oudin has preceded me by connecting his "resonator" with a D'Arsonval high-frequency apparatus. On the other hand, Sharpe,[8] at a date subsequent to the publications of my own observations, has connected a "resonator" with the static machine.

Still another source of ultra-violet rays has been observed by Leduc,[9] who found that they emanated from the negative end of a Geissler tube. I have found that if a piece of Willemite be placed at the negative end of the tube it will fluoresce, though not very vividly, but this phenomenon is rather puzzling, in view of the fact that the ultra-violet rays are not supposed to traverse glass, and if it, indeed, be those rays that have induced fluorescence, they must have been generated outside the tube and due to the electric stress, with, of course, the possibility that they are not ultra-violet rays but *x*-rays or cathode rays.

So much has of late appeared in print in relation to the treatment of cutaneous affections by *x*-rays that it would be a waste of time to exploit the matter further, other than to remark that many of the cases treated could have been handled to much better advantage by means already well known to the profession. I allude more particularly to cases of lupus and epithelioma. In the vast majority of these cases, excision, curettage and actual cautery, potential, caustics, etc., will yield equally good results and do so more quickly and economically; and good surgery and common honesty demands that they should be employed when available rather than the tedious, expensive, and, sometimes, dangerous application of the *x*-rays. In this respect I am in full accord with the recently expressed views of Robinson.[10] I am further confirmed in this by the opinion of Walsh,[11] who is a dermatologist as well as an experienced *x*-ray worker.

He writes as follows:

"It is evident, then, that we have in the focus-tube rays an agent capable of acting powerfully upon the skin and its appendages. At the same time, while similar effects can be obtained by simpler and safer means, the action is so uncertain, so difficult to regulate, and so apt to be attended with serious complications, that it is not likely to have any but an extremely limited application to the therapeutics of the cutaneous surface."

There are many cases, however, in which few surgeons would have the hardihood to use either the knife, the actual cautery or caustics. To these, therefore, the *x*-ray applications should be confined.

The terms "chemical" rays and "actinic" rays are nowadays frequently met with, and I regret to say are not always used by writers with discriminating accuracy, and some I find have but a vague conception of their true meaning. It is an old observation that if hydrogen and chlorine be brought together in a free state they will instantly combine to form hydrochloric acid if exposed to sunlight, and it has been found that this combination is much more readily brought about by the blue-violet rays with wave-lengths of, say, 0.48μ to 0.40μ than with the red-yellow rays with wave-lengths of 0.75μ to 0.58μ. The blue-violet, therefore, were termed "Chemical" rays. In the early days of photography when iodide of silver collodion plates were alone in use, it was found that the rays of shorter wave-lengths (blue-violet) were alone capable of impressing the photographic plate, that is, with any exposure of reasonable length, and hence these rays were termed "actinic." The same is true of the ordinary bromide of silver plates in use to-day. It is not a difficult matter, however, to prepare plates that will be as fully sensitive to the yellow rays as to the blue, and they can even be made extremely sensitive to red. All the visible rays, therefore, are to a certain extent actinic, and this term can no longer be applied with propriety to any definite or restricted portion of the spectrum.

The terms "phototherapy" and "light treatment" when applied to the Finsen methods are, strictly speaking, inaccurate, insomuch as the efficient agent is the non-luminous ultra-violet radiations. There is, however, a perfectly proper use of these names, that is to say, when they are used in connection with the luminous and colored rays. These radiations may be placed in two distinct groups, one consisting of the less refrangible rays including red to yellow (R-Y rays), and those that are more refrangible the blue to violet (B-V rays).

It will be noted that there is a gap between these two groups, namely, the green portion of the spectrum. I have failed to find that the green rays have any friends, and I am, therefore, unable to say anything in their favor or otherwise. As regards the two groups above mentioned it is claimed that the R-Y rays exert a calming effect in conditions of mental excitement, and that they also exercise a very beneficial action in exanthematous diseases, and more especially in smallpox, reducing the fever and lessening the suppuration.

These rays are most readily obtained by passing sunlight or strong artificial light through a variety of red glass known as "ruby," which permits but few if any of the more refrangible rays to pass.

The B-V rays appear to act as a general tonic and energizer, and to be specifically useful in tuberculosis. Sciascia[1] reports the following:

"A child of nine years of age had suffered for two months with low fever, anorexia, vomiting, wandering pains in the abdomen, and intestinal disturbances, and for the last forty days notable distension of the abdomen. There were also lymphatic engorgements in the cervical, axillary, and inguinal regions, with nodosities among the abdominal lymphatics. The diagnosis was tuberculous peritonitis.

"No treatment was employed, except daily exposure to condensed chemical rays from the sun. At the end of three months the symptoms and physical signs had disappeared, and the patient was again in good health. This history is accompanied with two photographs, one showing the child with marked distension of the abdomen, but otherwise in a state of extreme emaciation, while the second photograph, taken three months later, represents a child entirely free from the former evidences of ill-health."

I must confess that this case has made a strong impression on me, as it shows conclusively, assuming the facts to be as stated, the powerful influence of the B-V rays on tuberculosis. There is beside this considerable evidence from other sources as to the beneficial action of these rays, and it certainly seems that a thorough and exhaustive trial of the "blue-light treatment" should be made by those who are in the way of meeting with cases of this disease. Before doing so, however, the observer should make himself thoroughly familiar with the physical behavior of the colored rays, and their already ascertained action on plants and animals, and I would strongly advise him to consult the recent essay by Bleyer.[12]

Under the title radio-praxis the physiological and clinical phenomena of radiant heat deserve notice, but neither space nor time are at my command for this purpose, and I believe that I cannot do better than refer the reader to the carefully conducted experiments of Kellogg.[13]

Returning now to the therapy of certain cutaneous lesions, it may be said that we already have a pretty clear idea of the realm occupied by *x*-rays, and a very satisfactory knowledge of the proper technic, but we cannot say quite the same concerning the ultra-violet radiations. A number of points still need further elucidation:

1. Are the ultra-violet radiations as effective as the *x*-rays in the treatment of superficial malignant lesions?

2. Is the low-tension arc the most effectual means for generating the ultra-violet radiations and whatever goes with them?

3. Is the high-tension arc or condenser spark equal or superior to the low-tension arc in its therapeutic effects?

4. Is the spark from a coil more effective than that from a static machine, or *vice versa?*

5. Is the hyperstatic spark with its ultra-violet accompaniments equal in therapeutic efficacy, or superior to the other devices for the production of ultra-violet radiations?

To these problems we must look to the future for an answer.

There is still another class of radiations which during the last few years has excited the profound interest of chemists and physicists. I refer to the so-called Becquerel rays. It has long been known that preparations of uranium emitted actinic rays; that is, radiations capable of affecting photographic plates. Later it was observed that pitchblende, one of the uranium ores, possessed this faculty to a higher degree than uranium itself. It was then naturally inferred that pitchblende contained some definite radio-active substance that could possibly be isolated from the pitchblende and obtained in a state of greater or less purity. Further research led to the separation of three substances, each possessing intense radio-activity, but differing from each other in some minor respects. These have received the names radium, polonium, and actinium. At the present time one can obtain a "radio-active sodium" said to be twenty-five times as active as pitchblende for twenty-five cents a gram; also a "radio-active calcium" at the same price, and also a "radio-active *substanz B*." two hundred times as active as pitchblende. This costs four dollars and a half a gram. A still more refined preparation, said to be five or six thousand times as active as pitchblende is quoted at $200 a gram, equivalent to more than $5,000 an ounce.

The rays emitted from these bodies will pass through glass and even thick paper, so that a photographic plate protected by a double thickness of non-actinic paper will be affected by the radiations from the substance contained in a vial laid upon the plate. Preparations of thorium in like manner are capable of emitting these rays. It has been found that the Becquerel rays from the specially active preparations will exert a destructive action on the skin, even when not in actual contact with it, and without any appreciable loss of substance.

In a recent article, referring to the effects of the Becquerel rays on the tissues, Oudin[14] expresses the opinion that they are in reality *x*-rays, and bases his view on the following reports, and his own personal observations:

In October, 1900, Walkhoff (*Phot. Rundschau*) published a note stating that after the application of a radio-active substance he had an erythema similar to that produced by Röntgen rays. Giesel, in December, 1900 (Deutsche chem. Gesellschaft), stated that he applied a celluloid capsule containing 0.27 gram of bromide of barium and radium for two hours to the inner surface of his arm. After a few days an erythema appeared and increased for two or three weeks, became pigmented and was a long time in disappearing.

Early in the year 1901 M. Becquerel placed a small glass tube containing a few decigrams of radioactive substance in his vest-pocket and kept it there about two hours. Two weeks later an erythema appeared on the abdominal walls, corresponding to the position occupied by the glass tube. The erythema increased slowly and was followed by an ulceration.

M. Curie kept a small quantity of the same substance, wrapped in guttapercha, in contact with his arm for two hours. This was followed by erythema and ulceration.

Mme. Curie held a small quantity, sealed in a glass tube and covered by a metal case, in the palm of the hand for half an hour. Two weeks later there appeared an intense erythema, followed by a large bulla.

Oudin states that in the three cases seen by him, the lesions were markedly similar to those produced by *x*-rays. In the case of M. Curie it was six months before the ulceration was completely healed. A year later, after working for some time in the preparation of radio-active substances, he again suffered from their effects, the lesions exactly resembling those frequently met with in *x*-ray workers.

It is, however, by no means certain that the radium emanations are composed entirely of *x*-rays, but it is believed by some that they are a mixture of *x*- and cathode-rays.[15]

Knowing the powerfully destructive effects of these radiations on normal tissues, we are naturally fascinated by the thought that we may be able to utilize their powers for the modification of carcinomatous and lupoid processes, and thus avoid the inconvenience and expense of the present *x*-ray technic. There is, however, one serious difficulty in the way, namely, our inability to determine the precise amount of radiant energy exerted by any given preparation. In other words, we cannot exactly dose the application. Great as is the difficulty in dosing an *x*-ray exposure, it is vastly greater when we undertake to utilize the radio-active substances that at present are furnished commercially.

Concerning these rays, Ramsay,[16] in a recent article, concludes as follows:

"Whatever may be the true explanation of these mysteries, it cannot be denied that they form the beginnings of what may, and most certainly will, affect the material welfare of the human race. When we consider the beginnings made by Gilbert, by Franklin, by Volta, and by Faraday, and contrast them with the outcome of their discoveries, the electric telegraph and the dynamo machine, we cannot avoid the inference that the future has in store even greater developments than these. It is true that investigators like Hertz, Lenard, Becquerel, and the Curies do not make practical application of their discoveries; but there is never any lack of men who discover their practical value and apply them to ends useful to mankind; all the more reason, therefore, that every encouragement should be given to the investigator, for it is to him that all our advances in physical and material well-being are ultimately due."

FEEDING IN EARLY INFANCY.
HOME MODIFICATION OF MILK.

BY JOSEPH E. WINTERS, M.D.,
NEW YORK.

PROFESSOR OF THE DISEASES OF CHILDREN, CORNELL UNIVERSITY MEDICAL COLLEGE (IN NEW YORK CITY).

OF children born, one-third die within three months.* This startling fact makes improved methods of feeding in early infancy mandatory. That such improvement is not difficult of attainment will be made conclusive.

For a new-born child there is but one perfect food, the milk of a healthy mother. Attentive elaboration of two physiological facts precedes consideration of a substitute: (1) Difficulty of supplying a substitute adapted to existing conditions at birth. (2) Benefit to mother of lactation for a short period after child-birth.

Inherent Difficulty of Providing a Substitute for Mother's Milk, at the Beginning of Lactation, Adapted to the Peculiarities of a New-born Child.—Proteid is the nitrogenous constituent of milk on which growth and development depend, and which contains, in organic combination, minerals for construction of bone. No formation of tissue for fresh growth can occur without proteid.

Woman's milk and cow's milk contain two proteid constituents, albumin and casein. Albumin is not coagulated in the stomach by rennet. It is readily absorbable. Casein is coagulated into firm, compact masses. It is not digestible for a young child.

Albumin forms two-thirds of the proteid of woman's milk.

Casein forms four-fifths of the proteid of cow's milk.

WOMAN'S MILK.		COW'S MILK.	
Albumin	1.23	Albumin	0.53
Casein	0.50	Casein	2.88
Proteid	1.82	Proteid	3.41

Diluting cow's milk so as to bring casein within the digestive limits of a new-born child, causes deficiency of proteid for growth.

Woman's milk at the beginning of lactation (colostrum) is rich in readily absorbable proteid. Colostrum contains little or no casein. Change from colostrum to milk takes place ten days to two weeks after birth. Now, readily absorbable proteid decreases in quantity. As the milk becomes older, less easily absorbable proteid augments. This proteid calls forth considerable digestive effort.

The stomach of an infant increases rapidly in size during first two months of life, slowly in next two months; it is then comparatively quiescent until after the sixth month.

Capacity of stomach: Birth, 1 ounce; one month, 2½ ounces; two months, 3½ ounces.

At the end of the second month of life an infant's stomach is not only a more perfect receptacle for food, but its function has correspondingly developed. With increase in size and function of the stomach, a child becomes adapted to digestion of food other than breast milk. After the second month, a child can readily digest properly modified cow's milk.

Mortality in infants under one year is so great, that an equally high death rate is not again recorded until about the age of eighty years!

Seventy-five per cent. of deaths in first year occur in first half. Of these a large proportion die in first month. Mortality is highest in first week, falls enormously in second week, remains nearly stationary through third, and shows a considerable decline in the fourth week. Mortality in second month is only a small fraction of that in first month.

The astounding mortality in the first year of life proceeds from disease which had its inception when the stomach was unequal to any function except that of absorption. It results from improper methods of feeding.

During the siege of Paris (1870–71), while the general mortality was doubled, that of infants was lowered 40 per cent., owing to mothers being driven to suckle their infants!

In a new-born babe there is marked loss of weight the first day of life, a slight loss the second day, the greatest loss being reached at the beginning of the third day. This, for the most part, is due to discharge of meconium and urine, and evaporation from cutaneous surface. The third day there is slight gain. This gain coincides with an abundant secretion of breast milk. Initial loss is eight to ten ounces. At the end of the seventh day a child should have regained its birth weight, showing immediate assimilation of proteid-rich food.*

Increase in length and weight of a child should progress steadily from the beginning of the third day. Length increases most rapidly the first week of life.

Maximum gain is in the second month, when it is four to seven ounces each week, often averaging an ounce a day.

During the period of rapid growth a child's food

* *Journal of the American Medical Association*, August 2, 1902, p. 252.

* There is a definite and unfailing relationship between growth and percentage of proteid in milk. The calf doubled its weight in forty-seven days with 4 per cent. of proteid in milk; the lamb in ten days with 7 per cent.; the puppy in eight days with 8.28 per cent.; the kitten in five days with 9.33 per cent. of proteid in milk. The first and second days after child-birth the secretion of the breasts contains 8.6 per cent. of *albumin;* from the third to the seventh day 3.4 per cent.; from the eighth to the fourteenth day 2.5 per cent. (London *Lancet*, 1898.) If the above percentages are even approximately true, it is impossible to duplicate the first secretion of the breasts. The sooner after birth a child is put to the breast the less will be the loss in vigor. Immediate nursing saves many lives.

should be rich in proteid and minerals—building materials.

Intrauterine development is on proteid and minerals from blood of mother. At delivery, the blood stream is diverted to the breasts. Milk-proteids are derivatives of blood-proteids. Lactalbumin is similar to serum-albumin of blood. The breasts extract minerals from the blood in the proportions contained in tissues of child.

To a child beginning an independent existence, a food which is readily absorbable and rich in components for growth is of propitious issue.

Observe Nature's sublime purpose in providing for the new-born babe a food absorbable without digestive effort, and rich in proteid and minerals for immediate development!

The calcium phosphate, magnesia, sodium, and potassium chloride, contained in greater quantity than in milk of a later period, has a laxative effect and causes discharge of meconium.

With maternal nursing mortality is lower than with wet nursing, owing to the peculiar properties of colostrum milk.

Analysis and synthesis cannot provide a substitute having the composition and properties of mother's milk, at the beginning of lactation; a food adapted to the undeveloped and functionless state of the digestive organs, the immediate nutritive and developmental needs of a child at the threshold of life.

Our first proposition, inherent difficulty of providing a substitute for mother's milk at the beginning of lactation, adapted to the peculiarities of a new-born child, is clear and conclusive. During the period of rapid growth; of undeveloped digestive organs; of greatest danger of death from asthenia, a child's food should be that which Nature provides.

Lactation for a Short Period after Childbirth Exerts Salutary Influence on Mother.—Before impregnation the uterus measures 2¾ inches in length, 1¾ in breadth at its upper and wider part, less than an inch in thickness; its weight is from an ounce to an ounce and a half.

At the end of pregnancy it measures 14 inches in length, 10 in breadth, 9½ inches in thickness, and weighs 2 to 2½ pounds.

Blood vessels, formerly microscopical, are large, tortuous canals, size of extremity of little finger. The organ has increased in size twenty-five times.

After labor it should diminish in weight one pound in two weeks. It should be restored to its normal size six weeks to two months after delivery. Restoration is brought about by uterine contraction.

Muscular contraction, by obliterating vascular canals and cutting off blood supply, causes fatty degeneration and absorption of superabundant tissue. If the contractions are not sufficiently powerful, the blood channels are not obliterated: Each time the infant seizes the nipple the uterus contracts powerfully—it is perceptible to the hand applied to the abdomen. This reflex stimulation is applied ten times every twenty-four hours. It is maintained each time one-third of an hour. When the reflex stimulation of suckling is lacking, resolution is delayed. Delayed resolution and subinvolution, are the initial causes of the majority of the diseases of the uterus.

Lactation for a short period after child-birth forestalls congestion, enlargement, and displacement of the uterus. Uterogestation and delivery are but half the process of generation to a mother: To complete this process a brief period of lactation is an essential supplementary.

The time required for uterus, vagina, and articulations of pelvis to recover from changes induced by pregnancy and labor, should be the lying-in period. This coincides with the time of proteid-rich secretion of breasts; of undeveloped digestive organs and functions of child; of rapid growth; of greatest danger of death from asthenia.

During regeneration a mother should be in a state of physical and mental repose and comparative seclusion; free from care, anxiety, and excitement—no visitors, no discussion about her child, conditions favorable to successful, healthful lactation.

With proper regulation of diet before confinement, and during lying-in period, every mother can nurse successfully during the weeks when it is of so much moment to herself and her child that lactation should be stimulated.

There is much positively erroneous belief regarding inability of mothers to nurse, and much mistaken practice founded on it.

Weaning at the actual commencement of lactation, through misapprehension, is not uncommon. A child has frequent green stools; without reflecting that richness in salts of first secretion of the breasts is for clearing out meconium, it is concluded that the milk disagrees, and the child is weaned. An infant has discomfort from one cause or another, often from superficial soreness and tenderness, consequent on having been forced through a narrow, bony outlet. This is misinterpreted colic, and hot water given. It next cries from hunger, but refuses to nurse. Nursing is laborious and fatiguing. As long as a child can get anything, even water, from a bottle, it will not nurse.

A muscular cushion exists in the cheek for drawing the breast. This is a large, well-developed, strong muscle at birth. How marvelous is Nature! A child nurses for a few moments and becomes fatigued; it stops to rest fatigued muscles and falls asleep, or closes its eyes to exclude light, and this is mistaken for sleep. It is removed from the breast. Soon it is restless from hunger; but colic is suspected, hot water dispensed, and again the breast is refused.

That a new-born babe may be made to nurse by rule five or ten minutes, and no longer, should not be considered seriously by those responsible for its life.

To weigh a child, put it to the breast ten minutes, remove it while nursing greedily, and by again weighing, decide that it has nursed two ounces or three ounces, and when it cries from hunger that the milk disagrees, is well-nigh incredible, yet not infrequently practised. Under such regimen a child was failing alarmingly. Permitted to nurse until sated, it gained thirteen ounces the first week, twelve the next, and fourteen ounces the third week. With nursing abridged to two minutes (!) a child had scarcely slept for days and nights. After nursing until it would take no more, it slept uninterruptedly from 8.40 P. M. until 5 A.M.

Nursing by clock and scale is the culmination of absurdity.

Leave a child at the breast until satisfied, even if it falls asleep several times. When satisfied, it drops the nipple, and its head falls away from the breast. A little thought and tact will enable anyone to induce a child to nurse.

Because a child does not nurse by rule and with avidity, it should not be concluded that it has colic and that the milk disagrees. The milk of every healthy mother agrees with her child. When it disagrees, the fault lies not with mother or child.

Misguided solicitude is common. Officiousness and fussiness concerning the baby may arouse unnecessary anxiety and limit secretion of the breasts. An outsider who should not be admitted to the mother's chamber may be accountable for disturbed secretion. Inconsiderate comments on small deviations—curds,

green stools, colic, sleeplessness, lack of gain, deficient milk supply, and similar remarks, create great alarm in a young and inexperienced mother, and have sacrificed many lives. It is not allowable or tolerable to advert to one of these in the presence of a mother.

Place the child in a darkened room apart, where there is absolute quiet, that it may sleep uninterruptedly except when taken to the mother for nursing, after which replace it immediately in its bassinet. It should not be handled, fondled, or talked to. Nature's demands alone should be attended to.

Where the nipples are small or inverted, they should be drawn out and formed before accouchement. With this preparation and putting the child to the breast at once, nursing is feasible even under these discouraging conditions.

How Long after Birth Is Mother's Milk a Perfect Food for a Growing Child?—Its composition as lactation advances, and the physiological necessities for growth are competent criteria.

Proteid diminishes with advancing lactation. At end of colostrum period there is a marked decrease. It then lessens slowly and steadily until end of second month. After the second month there is decided and rapid diminution. Minerals share the impairment. Proteids and inorganic salts are organically combined. Their ratio is unchangeable. Woman's milk as it becomes older is impaired in materials for growth.

In a child exclusively breast-fed maximum gain is during the second month. Growth languishes with diminution of proteid content. Proteid and minerals are no longer adequate to demands for growth. It is physiological to wean as soon as practicable after the second month.

Conclusions.—Mortality at the very commencement of life in infants artificially fed; its obvious connection with the undeveloped and functionless state of the digestive organs; the inimitable composition of the first secretion of the breasts; the physiology of restoration of the uterus to its pristine condition after pregnancy and child birth, implant an ineradicable conviction, that lactation admits of no dispensation during the period of uterine regeneration.

It is likewise manifest that nature did not purpose protraction of lactation eight to ten months. Unnatural extension has been deterrent of lactation.

For two months from birth mother and child are mutually dependent. Advantage is equal. Severance impairs both. Observance of interdependence for two months would lower infant mortality to minimum; postpartum ailments of mothers would disappear.

The poorer classes should not be counseled to wean at end of second month, for economic reasons, and owing to difficulty of securing pure, fresh, sweet milk for feeding during heated term. Even with them nursing should not be extended beyond five to six months. A child born in the spring should be weaned in the early autumn, and one born in the autumn should be weaned before the summer.

The impression that lactation is unfavorable to health and exhausting, is erroneous. The strongest, healthiest, longest lived, youngest in appearance for their years, are women who have had many children, and have nursed them. This may be verified in prominent families in all parts of the world.

Artificial or Substitute Feeding.—It is natural that bottle feeding should begin in early infancy, and in a large number of cases there is no alternative but artificial feeding from birth. The physician has constantly to face the question of a substitute for human milk.

A fac-simile of woman's milk is its only substitute.

Unfaithfulness in copying defies physiology—Nature.

A Duplicate of Woman's Milk Must Conform Unerringly to the Appended Laws Prescribed by Nature:

First—The constituents must be identical with those in human milk: They must be proportionate to the demands for growth.

Second—These constituents must be of animal origin: Constituents other than those from an animal source are deficient in qualities essential for growth and development.

Third—Vitality of mineral and proteid constituents must be unimpaired: A temperature much above that of blood impairs vitality, by dissolving the loose chemical union of mineral and proteid in milk. In this state minerals are not assimilated.

Fourth—It must contain nothing foreign to milk: Anything adventitious vitiates the substitute.

These are laws of Nature, inflexible, unalterable, infallible, eternal. Infringement of them is the cause of the infamous, the shameful, the humiliating mortality from artificial feeding.

The only food which can be made to fulfil Nature's laws is cow's milk. Human milk and cow's milk contain the same constituents. They differ in their proportions.

Human milk has a low percentage of proteid, a high percentage of fat. In cow's milk these constituents are in nearly equal proportions. The perplexing, troublesome characteristic of cow's milk is the indigestibility of its proteid for a new-born child. During first three days of life a child cannot digest more than one-fourth of 1 per cent. of the proteid of cow's milk; during succeeding days of first week, one-third of 1 per cent. In second week, one-half of 1 per cent.; in third week, three-fourths, and in the fourth, fifth, sixth, seventh, and eighth weeks, 1 per cent.

Relative Proportion of Fat to Proteid.—Of equal importance with a low percentage of proteid at the outset of a course of artificial feeding, is the relative proportion of fat to proteid.

With one-fourth of 1 per cent. of proteid there must be 2 per cent. of fat; with one-third of 1 per cent., 2½ of fat; with one-half of 1 per cent. of proteid, 3 per cent. of fat; with three-fourths of 1 per cent. of proteid, 3½ of fat, and with 1 per cent. of proteid, 4 per cent. of fat. Failure due to wrong relative proportions of these constituents is constantly confronted.

Conformation of proportions as indicated converts failure into success.

For low proteid combinations cream is necessary. Market cream is mostly centrifugal. An infant does not thrive on centrifugal cream. The centrifuge makes 6,700 revolutions per minute. Trituration alters cream.

Contrast it with cream of Nature's formation. Fat being lightest part of milk, tends to rise to surface, and forms a layer which is known as cream. This contains not fat alone, but all the constituents of milk, and is therefore simply milk containing an excessive amount of fat. Each fat globule by molecular attraction is surrounded by a stratum of proteid. This prevents them from uniting with each other.

Centrifugalization destroys the normal cohesive attraction of fat globule and proteid.

The stratum of proteid is wanting, fat globules become coherent.

Centrifugal cream must be nearly proteid-free.

As proteid contains the mineral bodies, centrifugal cream is deficient in inorganic elements. Skimmed

milk added is so beyond the digestion of a young child, that the percentage of proteid cannot be increased to requisite proportions.

Machine-made Cream.—In centrifugal cream, coherent fat globules are indigestible for an infant, and it is deficient in proteid and minerals for growth and development. Machine-made cream should not be used in feeding infants.

Like human milk, gravity cream has a low percentage of proteid, a high percentage of fat.

A fac-simile of woman's milk is readily produced from it.

The percentage of proteid and fat in cream is contingent on the length of time milk stands before removing cream, and the quantity taken from each quart bottle.

To insure correct percentages of proteid and fat for early infant feeding, cream must be sixteen hours old, and only top *half* ounce removed. Removal without displacing is made practicable by keel-shaped dipper of "Noël Nursery Table." With no other device is this feasible.

The subjoined table shows the percentages of proteid and fat in different cream layers, and the ratio of proteid to fat, from actual analyses of milk as sold in New York City (about twenty-four hours after bottling) in September and October, 1902. The analyses were made at Havemeyer Hall by Mr. Henry C. Sherman, Ph.D.

FAT AND PROTEID AS FOUND IN SERIES OF ANALYSES, SEPTEMBER TO OCTOBER, 1902.

PORTION TAKEN	FAT	PROTEID	RATIO
Upper ½ ounce	24.8	3.1	8:1
Upper 1 ounce	23.1	3.2	7.2:1
Upper 2 ounces	21.4	3.3	6.5:1
Upper 4 ounces	20.1	3.4	5.9:1
Upper 6 ounces	18.6	3.5	5.3:1
Upper 8 ounces	16.7	3.6	4.6:1
Upper 12 ounces	12.1	3.7	3.3:1
Upper 16 ounces	9.4	3.8	2.5:1

The *ratio* of proteid to fat in different cream layers is of great practical importance for feeding in early infancy, where the proteid must be low, and the fat relatively high. *In the upper half ounce*, 1 to 8; *in the upper eight ounces*, 1 to 4½.

A young child cannot be successfully fed on modification of upper eight ounces—excess of proteid or deficiency of fat is unavoidable. Here has been a universal pitfall of physicians. To those who have been in the dark, this luminous ratio column shows the way to successful feeding.

To avoid disorder of digestion in a new-born child upper half ounce must be used. Fat indigestion in infants, so much prated about, is a myth. Properly modified cream is always well borne by the youngest and most delicate infant.

For young infants, milk should not be added to cream. Milk and cream do not unite. If shaken together, and then allowed to stand for a short time, separation is complete. The same occurs in the stomach. The stomach has practically to cope with whole milk. Many failures are due to this prevalent error.

The following percentages and relative proportions of fat and proteid must be adhered to for successful feeding:

	FAT	PROTEID
First three days	2.00	0.25
Succeeding days—first week	2.50	0.33
Second week	3.00	0.50
Third week	3.50	0.75
Fourth to eighth weeks	4.00	1.00
Ninth to twelfth weeks	4.00	1.25
Fourth month	4.00	1.50
Fifth and sixth months	4.00	1.75
Seventh, eighth and ninth months	4.00	2.00
Tenth and eleventh months	4.00	2.50
Twelfth month	4.00	3.00

In summer the strengthening must be more gradual, as follows:

	FAT	PROTEID
First week	2.00	0.25
Second week	2.50	0.33
Third and fourth weeks	3.00	0.50
Fifth and sixth weeks	3.50	0.75
Seventh week to end of third month	4.00	1.00
Fourth month	4.00	1.25
Fifth and sixth months	4.00	1.50
Seventh month	4.00	1.75
Eighth and ninth months	4.00	2.00

Formulæ for Home Modification of Bottled Milk (from actual analyses).—The percentage of proteid is higher in the autumn, hence the formulæ formerly published have been recast to conform to this.*

FORMULA NO. 1.

		COMPOSITION.
First, second, and third days:	Upper ½ ounce from each of two quart bottles of milk. Milk-sugar ⅚ ounce (about 3⅓ teaspoonfuls). Lime water, 1½ ounces. Filtered water, 9 ounces.	Fat, 2.00; Milk-sugar, 7.00; Proteid, 0.25.

Quantity at each feeding: First and second days ½ ounce; third day, 1 ounce.
Ten feedings, at 6, 8, 10, and 12 A.M., 2, 4, 6, 8, and 12 P.M., 4 A.M.

FORMULA NO. 2.

Fourth, fifth, sixth, and seventh days:	Upper ½ ounce from each of three quart bottles of milk. Milk-sugar, 1 ounce (about 4 teaspoonfuls). Lime water, 2 ounces. Filtered water, 10½ ounces.	Fat, 2.50; Milk-sugar, 7.00; Proteid, 0.33.

FORMULA NO. 3.

Second week:	Upper 2¼ ounces from one quart bottle of milk. Milk-sugar, 1 ounce (about 4 teaspoonfuls). Lime water, 2 ounces; Filtered water, 10 ounces.	Fat, 3.00; Milk-sugar, 7.00; Proteid, 0.50.

For chemical accuracy, the upper 7 ounces should be used in making Formula No. 4. Clinically, the upper 6 ounces proves better.

FORMULA NO. 4.

Third week:	Upper 6 ounces from one quart bottle of milk. Milk-sugar, 1.8 ounces (about 7 teaspoonfuls). Lime water, 4 ounces. Filtered water, 18 ounces.	Fat, 3.50; Milk-sugar, 7.00; Proteid, 0.75.

* For complete, detailed instructions consult "The Feeding of Infants; Home Guide for Modifying Milk." E. P. Dutton & Co., New York.

FORMULA No. 5.

Fourth to eighth weeks:	Upper 9 ounces from one quart bottle of milk. Milk-sugar, 2 ounces (about 8 teaspoonfuls). Lime water, 4 ounces. Filtered water, 19 ounces (or enough to make one quart).	Fat, 4.00; Milk-sugar, 7.00; Proteid, 1.00.

FORMULA No. 6.

Ninth to twelfth weeks:	Upper 11 ounces from one quart bottle of milk. Milk-sugar, 1.9 ounces (about 7½ teaspoonfuls). Lime water, 4 ounces. Filtered water, 17 ounces (or enough to make one quart).	Fat, 4.00; Milk-sugar, 7.00; Proteid, 1.25.

FORMULA No. 7.

Fourth month:	Upper 13 ounces from one quart bottle of milk. Milk-sugar, 1.8 ounces (about 7 teaspoonfuls). Lime water, 4 ounces; Filtered water, 15 ounces (or enough to make one quart).	Fat, 4.00; Milk-sugar, 7.00; Proteid, 1.50.

FORMULA No. 8.

Fifth and sixth months:	Upper 15 ounces from one quart bottle of milk. Milk-sugar, 1.7 ounces (about 6⅔ teaspoonfuls). Lime water, 4 ounces. Filtered water, 13 ounces (or enough to make one quart).	Fat, 4.00; Milk-sugar, 7.00; Proteid, 1.75.

FORMULA No. 9.

Seventh, eighth, and ninth months:	Upper 17 ounces from one quart bottle of milk. Milk-sugar, 1.4 ounces (about 5½ teaspoonfuls). Lime water, 4 ounces. Filtered water, 11 ounces (or enough to make one quart).*	Fat, 4.00; Milk-sugar, 6.50; Proteid, 2.00.

FORMULA No. 10.

Tenth and eleventh months:	Upper 21 ounces from one quart bottle of milk. Milk sugar, 1.1 ounces (about 4⅓ teaspoonfuls). Lime water, 4 ounces. Filtered water, 7 ounces (or enough to make one quart).	Fat, 4.00; Milk-sugar, 6.00; Proteid, 2.50.

FORMULA No. 11.

Twelfth month:	Upper 25 ounces from one quart bottle of milk. Milk-sugar, 0.7 ounce (about 2¾ teaspoonfuls). Lime water, 4 ounces. Filtered water, 3 ounces (or enough to make one quart).	Fat, 4.00; Milk-sugar, 5.50; Proteid, 3.00.

Formulæ for Home Modification of Bottled Milk for Feeding During Summer Months (from actual analyses).

FORMULA No. 1.

		COMPOSITION.
First week:	Upper ½ ounce from each of two quart bottles of milk. Milk-sugar, ⅚ ounce (about 3⅓ teaspoonfuls). Lime water, 1½ ounces. Filtered water, 9 ounces.	Fat, 2.00; Milk-sugar, 7.00; Proteid, 0.25.

Quantity at each feeding: First and second days, ½ ounce; third day, 1 ounce. Ten feedings, at 6, 8, 10, and 12 A.M., 2, 4, 6, 8, and 12 P.M., 4 A.M.

FORMULA No. 2.

Second week:	Upper ½ ounce from each of three quart bottles of milk. Milk-sugar, 1 ounce (about 4 teaspoonfuls). Lime water, 2 ounces. Filtered water, 10½ ounces.	Fat, 2.50; Milk-sugar, 7.00; Proteid, 0.33.

FORMULA No. 3.

Third and fourth weeks:	Upper 2¼ ounces from one quart bottle of milk. Milk sugar, 1 ounce (about 4 teaspoonfuls). Lime water, 2 ounces. Filtered water, 10 ounces.	Fat, 3.00; Milk-sugar, 7.00; Proteid, 0.50.

For chemical accuracy, the upper 7 ounces should be used in making Formula No. 4. Clinically, the upper 6 ounces proves better.

FORMULA No. 4.

Fifth and sixth weeks:	Upper 6 ounces from one quart bottle of milk. Milk-sugar, 1.8 ounces (about 7 teaspoonfuls). Lime water, 4 ounces. Filtered water, 18 ounces.	Fat, 3.50; Milk-sugar, 7.00; Proteid, 0.75.

FORMULA No. 5.

Seventh week to end of third month:	Upper 9 ounces from one quart bottle of milk. Milk-sugar, 2 ounces (about 8 teaspoonfuls). Lime water, 4 ounces. Filtered water, 19 ounces (or enough to make one quart).	Fat, 4.00; Milk-sugar, 7.00; Proteid, 1.00.

* The age at which cereal should be added to the food was considered last year: "Adaptation of Food to the Necessities of the Growing Organism."—MEDICAL RECORD, January 25, 1902, page 121.

FORMULA No. 6.

Fourth month:	Upper 11 ounces from one quart bottle of milk. Milk-sugar, 1.9 ounces (about 7½ teaspoonfuls). Lime water, 4 ounces. Filtered water, 17 ounces (or enough to make one quart).	Fat, 4.00; Milk-sugar, 7.00; Proteid, 1.25.

FORMULA No. 7.

Fifth and sixth months:	Upper 13 ounces from one quart bottle of milk. Milk-sugar, 1.8 ounces (about 7 teaspoonfuls). Lime water, 4 ounces. Filtered water, 15 ounces (or enough to make one quart).	Fat, 4.00; Milk-sugar, 7.00; Proteid, 1.50.

FORMULA No. 8.

Seventh month:	Upper 15 ounces from one quart bottle of milk. Milk-sugar, 1.7 ounces (about 6⅔ teaspoonfuls). Lime water, 4 ounces. Filtered water, 13 ounces (or enough to make one quart).	Fat, 4.00; Milk-sugar, 7.00; Proteid, 1.75.

FORMULA No. 9.

Eighth and ninth months:	Upper 17 ounces from one quart bottle of milk. Milk-sugar, 1.4 ounces (about 5½ teaspoonfuls). Lime water, 4 ounces. Filtered water, 11 ounces (or enough to make one quart).*	Fat, 4.00; Milk-sugar, 6.50; Proteid, 2.00.

* The age at which cereal should be added to the food was considered last year: "Adaptation of Food to the Necessities of the Growing Organism"—MEDICAL RECORD, January 25, 1902, page 121.

Pasteurization; Proprietary Foods; Cereals.—Animals in which milk alone is a sufficient food die of inanition when the minerals are extracted, and the result is the same with the minerals added to the other constituents, after the organic union of mineral and proteid has been broken up.

Minerals to be Assimilated Must be in Organic Combination with Proteid.—Proteid for Organization and Formation of Tissue Must Have Minerals in Chemical Union.†

In every part of the organism, minerals are united to the proteids. If this union is dissolved, the structure is dead. If mineral and proteid are not in organic combination in food, no formation of tissue for fresh growth can occur.

Pasteurization dissolves the loose chemical union of mineral and proteid in milk.

Obedient to this invincible, this inexorable law of chemical physiology, it is a duty incumbent on every physician to discard the pasteurizer absolutely and forever. What God hath put together let not the pseudo-scientist cut wide asunder!

Food in which the chemical union of mineral and proteid has been dissolved will not sustain life, and food in which this union is partially dissolved, only half sustains life.

Much obscure undefined derangement of health in children is traceable to this fault of diet.

Proprietary foods, pasteurized and sterilized milk, constantly furnish conspicuous, typical, sad examples of this food disorder.

Destitution of vitalized mineral and proteid is insuperable in manufactured food.

These foods are all misleadingly advertised as substitutes for milk. Milk is a living fluid—blanched blood. A substitute is as impossible as artificial blood.

Were a vitalized substitute for milk possible, it is uncalled for. With present enlightenment, by modification of cow's milk, an exact counterpart of human milk is made with facility.

Failure with cow's milk is due to faulty modification; the palpable error of adding milk to cream (see page 16); the incongruous combination of centrifugal cream and skimmed milk; lack of individualization in feeding; mixing foreign material. Intolerance of milk, the so-called "milk idiosyncrasy" of infants, is not *bona fide*. This absurd sentiment comes from lack of ability to modify milk properly.

A cereal, or a proprietary food added to milk, curtails supply of vitalized mineral and proteid.

Deprivation of mineral and proteid is the cause of rickets. When destitution is extreme, scurvy complicates rickets. Scurvy and rickets are identical. Both originate from this sole cause, and, according to the degree of impairment, will one or the other result. Coexistence is usual, scurvy supervening.

Deficiency of fat; presence of starch; mal-hygiene; climate; race; effect of northern climate on natives of tropical countries; heredity; concurrent disease—syphilis; tuberculosis, are not etiological factors of scurvy rickets. *Inadequacy of mineral and proteid as vitalized by the hand of nature is the sole factor.*

Physiological chemistry forbids the use of manufactured food, and of pasteurized milk, for infant feeding; or the deterioration of milk by barley or other cereal, for feeding in early infancy.

A fac-simile of woman's milk—a vital living fluid—is its only substitute. Unfaithfulness in copying vitiates the substitute.

When a child is nursed by mother six weeks to two months, and then weaned, artificial feeding should begin the fourth week, by the use of one feeding a day of two ounces of Formula No. 1. The second half of week, Formula No. 3, the same quantity. During fifth week, two feedings of 2½ ounces of formula No. 4; the sixth week, three feedings of Formula No. 5. From this time onward the food is strengthened as in a child artificially fed from birth.

Weaning, irrespective of the age of the child, should always begin with Formula No. 1. The amount is determined by the age. In a well-developed child of several months, strengthening may be rapid, especially in cool weather. In summer, strengthening must always be gradual.

Over-feeding is the most frequent difficulty in bottle feeding. Many mothers have an immoderate desire for an unusual child, and imagine a food strong in quality, or excessive in quantity, will compass this. To every such mother it should be made clear that when her child is thriving on a food, one-fourth of 1 per cent. more of proteid, or an additional half ounce, without strengthening, may cause serious and dangerous disturbance of digestion—so delicate are the digestive organs in young infants. Avoid-

† This chemico-physiological fact lays bare the absolute inanity of split proteid feeding.

ance of disorder of digestion is paramount in artificial feeding—the younger the child the more commanding its importance. For amendment, return to Formula No. 1 is indispensable. Priceless time for nutrition and growth has been sacrificed needlessly.

Acute illness in a bottle-fed child necessitates recourse to a weaker formula until the eve of convalescence. Digestive disorder is obviated, and clamoring for some innutritive patent food forestalled.

In acute diarrhœa, at once clear the bowels thoroughly with castor oil; for twenty-four hours after this is *completed*, give nothing but water, and then begin with Formula No. 1. Keep to this formula until looseness and fermentation have ceased. Then strengthen gradually until the formula in use before the illness began is reached.

With the above simple management, diarrhœa in a young infant is always promptly checked. Barley water, dextrinized gruel, and all unphysiological foods, are more baneful than in the normal state. Commendations of them are ungrounded and unscientific. The preposterousness of a diseased digestion being benefited by what is universally conceded to be pernicious in health! Giving cereals before the seventh month, in health or disease, is running counter to all the laws of physiology. He who flies in the face of physiology, places himself above Nature's laws; above the evident design and purpose of the Creator.

Sophists perpetuate unphysiological feeding, and the patent foods, their illogical writings being seized upon by traffickers and sent broadcast. Would that these prolific superficialists could rest from their pen long enough to meditate on the harm they are doing. Doctrinaires obscure a subject of perfect simplicity and clearness—feeding and its disorders—and send the death rate in young infants skyward every summer.

The most monstrous and singular anomaly is to withdraw the breast from a child with an acute diarrhœa. Diarrhœa in a breast-fed infant is never serious. With regulation of the habits and diet of the mother; freedom from care and anxiety, and proper intervals between nursing, it ceases at once. The devious practice of substituting for this physiological secretion some concoction of human device and fallible professional judgment, is the direct outcome of the dissemination of the writings of faddists.

With correct feeding (breast or bottle) diarrhœa (an[3] cholera infantum) never arise. Dietetic error is the sole cause. This shuts out the theory of specific germ origin. In its incipiency, diarrhœa is always absolutely controllable by the simplest management, which sets at naught all speculation as to serum treatment. Is it possible that practical physicians will ever seriously contemplate the control of a process of fermentation in twenty feet of intestine by serum treatment?

25 West Thirty-seventh Street.

The Microscopic Findings in Four Gasserian Ganglia Removed for Trigeminal Neuralgia.—Sidney I. Schwab says, that from the result of his researches, the following conclusions seem to be justified: (1) In six ganglia removed for trigeminal neuralgia, anatomic changes were found of sufficient importance to bring them in relation with the symptoms of this disease. (2) These changes in the cells do not point to them as the primary cause of neuralgia, but they may be taken to represent the effects of abnormal cell activity, the origin of which we are not able to point out. (3) The Gasserian ganglion is the anatomical seat of the chief symptom of trigeminal neuralgia, that is, the attacks of neuralgic pain.—*The Journal of Nervous and Mental Disease.*

PLASTIC ARTIFICIAL VITREOUS IN MULES' OPERATION.

REPORT OF CASES IN WHICH PARAFFIN HAS BEEN USED.*

By E. L. OATMAN, M.D.,
BROOKLYN, N. Y.
SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL, NEW YORK.

After the removal of an eye, the efforts of the ophthalmologist are put forth to mitigate, so far as possible, the subsequent effects of the operation. If an enucleation has been performed, the orbital contents will ultimately shrink so as to form but a poor support for an artificial eye. The severed ocular muscles, having nothing on which to exert their power, undergo atrophy. Little or no motion remains to the stump, while the immovable glass shell but emphasizes the defect it was designed to conceal. The play of all the facial muscles is so intimately associated with the movements of the eye, that when the influence of the ocular muscles has been eliminated by an enucleation, that side of the face will soon become flat and expressionless.

The primary cosmetic effect of an evisceration may be better than that of an enucleation, but it is far from being a satisfactory operation.

In 1885 Mules† of Manchester introduced to the profession a method that promised better results than has previously been obtained by either of the above operations. Briefly stated, it consists in removing the cornea, eviscerating the contents of the scleral cavity, into which a glass ball is inserted. The scleral opening is then closed over the ball, which, if it is retained, gives to the stump the form and motion of an eye. When the operation is successful its results are certainly almost ideal, the most important being, that by preserving the functions of the ocular muscles, mobility of the entire countenance is retained. It was soon discovered, however, that this artificial vitreous was sooner or later very apt to be extruded, the final result being similar to that obtained by an evisceration. Balls made from all sorts of material have been substituted for those of glass, but the results have not been materially modified, their final expulsion appearing to depend upon conditions other than their composition. At the present time the prevalent feeling among ophthalmologists regarding the operation of Mules is one of disappointment.

When, from any cause, a fistulous opening has once formed over an artificial vitreous, it resists all attempts at repair until the foreign body has been expelled. Under these circumstances it has always appeared to me that if a portion of the ball could be removed and the tension on the scleral walls relieved, we might hope for closure of the wound over the remainder.

The following plan of using some material for the artificial vitreous that can, if necessary, be removed piecemeal, has not, so far as I am aware, been previously employed.

Paraffin was selected as the most available material for carrying out this principle, which I applied in the case of Louisa K., age twenty-seven, who entered the Manhattan Eye and Ear Hospital January 17, 1902. The right eye was atrophic, with conical staphyloma of the cornea. An unsuccessful attempt to remedy the deformity had been undertaken in Germany. As the eye was irritable and unsightly, she asked for its removal.

The Mules' operation was performed in the usual

*Read before the New York Academy of Medicine, Section on Ophthalmology, November 17, 1902.

†P. H. Mules, *British Medical Journal*, December 19, 1885, page 1453.

manner, except that instead of glass a ball of paraffin was used to fill the vitreous cavity. The paraffin employed had a melting point of 120° F. The wound apparently closed satisfactorily; but it was soon discovered that a small fistula existed through which the plastic paraffin was slowly oozing. With a Daviel spoon, warmed in hot water, a considerable quantity of the paraffin was easily extracted through the opening, the edges of which were then freshened and sutured. No success attended this procedure, the fistula remained patent and the paraffin continued to escape. Two subsequent attempts to close the hole were followed by failure, and it was decided that paraffin was an unsuitable material for this purpose. No change for the better occurred until the paraffin had been discharged down to the level of the fistula, which, as the sclera had been stitched transversely, was about the center of the ball. When this point had been reached and about one-half of the paraffin had leaked away, the opening closed spontaneously and has remained closed since, a period of about ten months. The remaining paraffin forms an excellent cushion for a shell, and the stump has good motility. My colleague, Dr. Neil Hepburn, mentioned this case in the last meeting of the American Ophthalmological Society, and it was suggested there that the paraffin would gradually be absorbed. I doubt if any absorption has occurred, as I am unable to discover any change in the shape or size of the stump since the fistula closed.*

In preparing the ball the paraffin was first brought to the boiling point and then cooled very quickly, as in histological work, to prevent crystallization and the formation of bubbles. A ball was then roughly shaped with a knife. This was brought to the required size by placing it on a long needle and rotating it in the flame of an alcohol lamp, the action of the flame being controlled by occasionally dipping the ball into a cold bichloride solution.

Dr. Edgar S. Thompson, at my request, has since used a paraffin bead in one case. This paraffin had a melting point of 135° F. I understand, from Dr. Thompson, that the subsequent history of his case was similar to my own. There was an incomplete closure of the scleral wound, through which paraffin was discharged until it had sunk to the level of the fistula; then spontaneous healing occurred, and a very satisfactory stump remains.

Dr. D. Foster, House Surgeon of the Manhattan Eye and Ear Hospital, has also employed paraffin in one case when no glass ball of the proper size was at hand. In this case no fistula formed, and the result, four months after operation, is as good as can be expected in these cases.

The principle involved in this modification of Mules' operation requires a more extended trial before its value can be estimated.

The following immature conclusions may, however, be drawn from these three cases:

When fistula follows the Mules' operation it will close spontaneously if a sufficient quantity of the artificial vitreous can be removed. That which remains will form a good support for an artificial eye.

Paraffin used for this purpose is prone to produce fistula by softening and getting between the lips of the wound, or into the track of a suture. These accidents are to be avoided by using paraffin, or some modification thereof, that will not soften at body temperature; also by so suturing † the scleral wound that no aperture remains through which paraffin can exude.

A plastic material like paraffin will adapt itself to any inequalities on the surface of the glass shell, and ulceration from pressure is not apt to occur.

Paraffin beads are easily prepared, and may be used in special cases in which glass beads of the required shape or size are not obtainable.

*This criticism was based on the fact that the paraffin used in plastic nasal surgery is removed by absorption. The conditions, however, are hardly analogous. The paraffin mixtures used to supply subcutaneous loss of substance are very soft, so as to be injected by the hypodermic method. Owing to their semi-fluid consistency, they are eventually absorbed. The paraffin which is recommended for an artificial vitreous should have a very high melting point. Unless it can be sufficiently softened by body temperature, it is unlikely that absorption will occur.

† The scleral opening should be closed with silk sutures. Catgut has not proved satisfactory in this operation.

CLINICAL RESULTS WITH ANTI-STREPTOCOCCUS SERUM IN SCARLET FEVER.

By LOUIS FISCHER, M.D.,
NEW YORK.

VISITING PHYSICIAN TO THE WILLARD PARKER AND RIVERSIDE HOSPITALS OF NEW YORK CITY.

In 1896 a series of clinical investigations were commenced with Marmorek's serum, by Professor Baginsky of Berlin. Mild and malignant cases were chosen, and large and small doses were injected. The results, which were published at that time in a paper read before the Berlin Medical Society,[1] were disappointing, and the serum treatment was abandoned by him.

My own experience I owe to the courtesy of Baginsky during the summer of 1896, while abroad, and to continued experience in this city. In a paper read by me[2] before the Section of Pediatrics, New York Academy of Medicine, entitled "Clinical Experience with Antistreptococcus Serum," my conclusions were: "That we are not justified in either using or recommending the use of the antistreptococcus serum, and that the indiscriminate sale of this serum should be prohibited, until clinical experience established the true therapeutic value of the serum."

William H. Park, discussing my paper at that time, said that "the streptococcus serum differs from the antitoxin serum of diphtheria in one important feature—the bactericidal action of the streptococcus serum. The virulent streptococcus makes no more toxin than one that is not virulent; the ability to grow alone is what makes it virulent. It is, unfortunately true that the streptococcus serum is still very weak, but it is certainly a protective serum, as has been abundantly proved in the experiments at the laboratory of the health department, where a rabbit has been protected from septicæmia by sufficiently large doses of this serum. If, however, a rabbit became so septicæmic that the streptococcus could be obtained from the blood of the animal, the result of the injection of the serum was negative. It should always be born in mind that the streptococcus serum cannot be of any value except in inflammation due to the streptococcus."

In a study of 701 cases of scarlet fever, by Professor Baginsky associated with Dr. Sommerfeld, the streptococcus was demonstrated in 696 cases.[3]

The streptococcus was found on the pharyngeal mucous membrane, intra vitam.

About 100 cases were studied post mortem, and the streptococcus was found in the various organs in the heart blood, in the bone marrow, and so on. The constant presence of the streptococcus, although associated frequently with other germs, requires careful consideration. Because of this constant presence of a streptococcus its association with scarlet fever might be inferred.

Thus the conclusions of Baginsky and Sommerfeld

were that *the streptococcus is a distinct etiological factor in scarlet fever.*[4]

Reasoning by analogy, these investigators determined to produce a powerful serum. The standard adopted was to be on lines similar to that used in producing concentrated antitoxin for diphtheria.

Dr. Hans Aronson utilized a streptococcus taken from a child with a scarlatinal angina. From this germ he cultivated pure cultures. He also utilized a streptococcus taken from the bone marrow of a child that died of scarlet fever. From the cultivation of these germs Aronson was able to produce a very active and efficient immunizing serum.

A series of preliminary experiments were first tried on animals before Baginsky consented to its use in children. He found that "when mice were injected with a very virulent streptococcus bouillon, which usually $\frac{1}{100}$ millionth of a cubic centimeter proves fatal, it was found that they could easily withstand an infection of 0.000015 c.cm. of a most virulent streptococcus bouillon, if they were previously injected with 0.03-0.1 c.cm. of antistreptococcus serum."

Control mice, which were not previously injected with this new Aronson serum, all died when injected with the same fatal dose of streptococcus bouillon. Mice which were first injected with Marmoreck's serum and later received a fatal dose of the streptococcus bouillon all succumbed, proving that there was no healing property in Marmoreck's serum.

Aronson[5] used horses to produce immunity. The cultures of streptococci injected by him were derived from cases of scarlet fever.

In Germany, serum of which 0.01 c.c. when injected into mice will prevent septic infection of hog erysipelas is designated as a "normal serum." One c.c. contains one immunizing unit. The serum produced by Aronson, and utilized by Baginsky and myself, is equivalent to twenty times the strength of normal serum.

A series of interesting animal experiments are described in detail by Aronson. After an intra-abdominal injection with at least ten times as much as the ordinary fatal streptococcus quantity. The bacteria enter the circulation very rapidly, frequently in one hour, but positively after two hours the bacteria can be demonstrated in the blood.

Aronson advises amputating the tail and using the blood oozing therefrom for inoculating the nutrient bouillon. Aronson was able to save most of the animals by injecting five times the ordinary immunizing dose, two hours after a general infection had taken place. He also reports a series of successful results by injecting this healing serum even twenty-four hours after their infection.

It is interesting to note that in a series of animals which had first received a fatal injection of streptococcus culture, and on the following day an injection of a curing dose of serum, "living germs could be demonstrated in the blood at least twenty-four hours after such injection of serum." Thus Aronson reasoned that as long as the streptococcus could be demonstrated in the blood of these animals, that curing injections of antistreptococcus serum were indicated.

Aronson maintains in a paper read by him[6] *that an important therapeutic indication for the use of antistreptococcus serum was apparent to him as long as streptococci could be demonstrated in the blood of animals. He also insists that this point should be used as a guide in the determination of when to use and when to discontinue serum.*

How Is the Action of Antistreptococcus Serum Brought About?—Aronson maintains that even very powerful serum has no direct influence on streptococci. He has found that when virulent cultures of bouillon containing streptococci are inoculated into antistreptococcus serum, that they multiply, so that, although the serum seems to inhibit the growth of these germs slightly, there is *no direct specific destruction* which could be attributed to the serum. There is therefore something else in the animal body in addition to the serum, which stimulates cell activity, or probably by the direct cellular action, produces both an immunizing and a healing action. Another important point gleaned from the experiments of Aronson, shows that *when an animal was first injected with healing serum, the bacteria remained local and did not enter the general circulation, whereas in animals which were not previously injected the bacteria could be demonstrated in the blood, usually in one or two hours.*

This certainly proves that there are anti-bodies in the serum which prevents this general infection. These anti-bodies belong to a class called by Ehrlich amboceptors.

Another property of this new serum is that it produces typical agglutination of the streptococcus. This has never before been possible with antistreptococcus serum. Aronson insists that the agglutination described by him should not be confounded with microscopical agglutination. *The agglutination with this antistreptococcus serum is macroscopical, absolutely typical and is only possible when a concentrated serum is used.*

The identity of the various kinds of streptococcus found in man and in animals has been made the subject of an extensive study by Marmorek[7]. His conclusions based on his experiments show that the streptococci are all identical. Aronson maintains the same. The pneumococcus, which is morphologically similar to the streptococcus, *does not show agglutination properties.*

Baginsky's cases and their result with the new serum:

First group of cases treated	19 in all	—1 death = 5.3	per cent.
Second group	5 cases	—0 death = 0	"
Third group	18 cases	—1 death = 5.5	"
Fourth group	16 cases	—1 death = 6.2	"
Total	58 cases	—3 deaths = 4.2	"

Baginsky injected a series of moribund cases which proved fatal, thus he could increase his total by adding four more cases with four more deaths. One of these cases had tuberculosis, and another had pneumonia of a gangrenous type. Taking at random a series of two groups which were not treated with serum, he finds the following results:

First group	31 cases	—3 deaths = 9 .7	per cent
Second group	32 cases	—6 deaths = 18.7	"
Total	63 cases	—9 deaths = 17.3	"

Case I.—D. F., born September 28, 1898. Was prematurely born in the seventh month of pregnancy. She is an only child. Her parents are healthy. The family history is good. The mother has had one miscarriage at three months. This child was nursed at the breast about four months, and then put on Mellin's food. She has always had dyspeptic difficulties associated with continuous constipation.

Her teething began when nine months old. Her walking commenced at seventeen months. She then had pneumonia. Is susceptible to bronchitis and tonsilitis. Had a very bad attack of dysentery in the summer of 1901. Has a large hernia, for which she is treated by Dr. De Garmo. She had a second attack of pneumonia in October, 1902.

Adenoid vegetations were recently removed by Dr. H. Jarecky, after which the child's condition was normal. She is a very nervous child, and has always

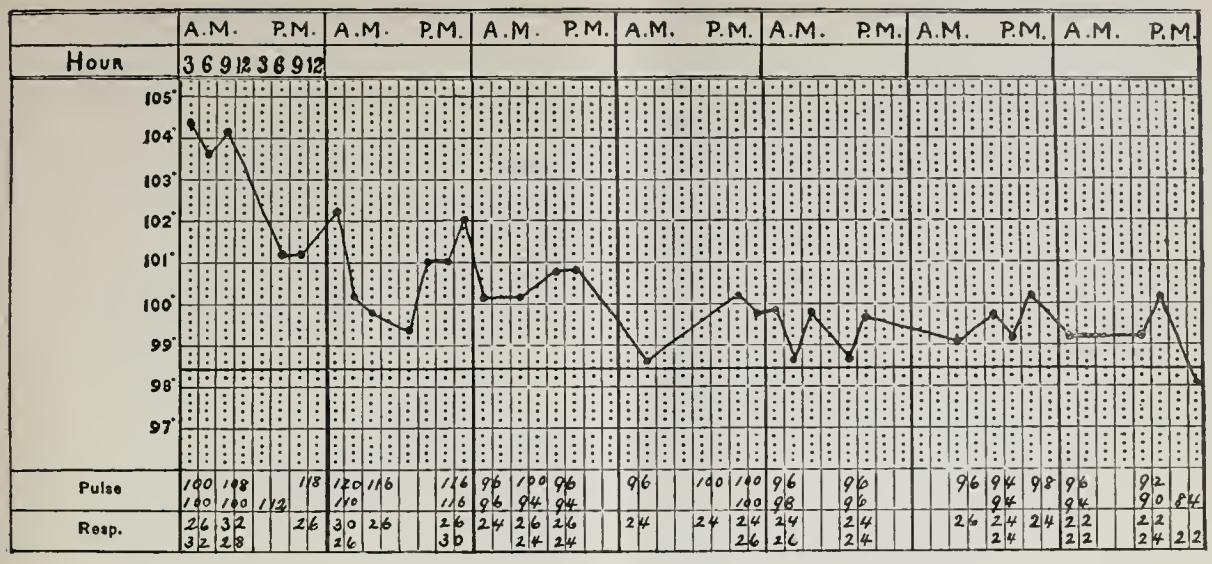

CHART 2.—CASE I. SECOND WEEK AFTER SERUM TREATMENT.

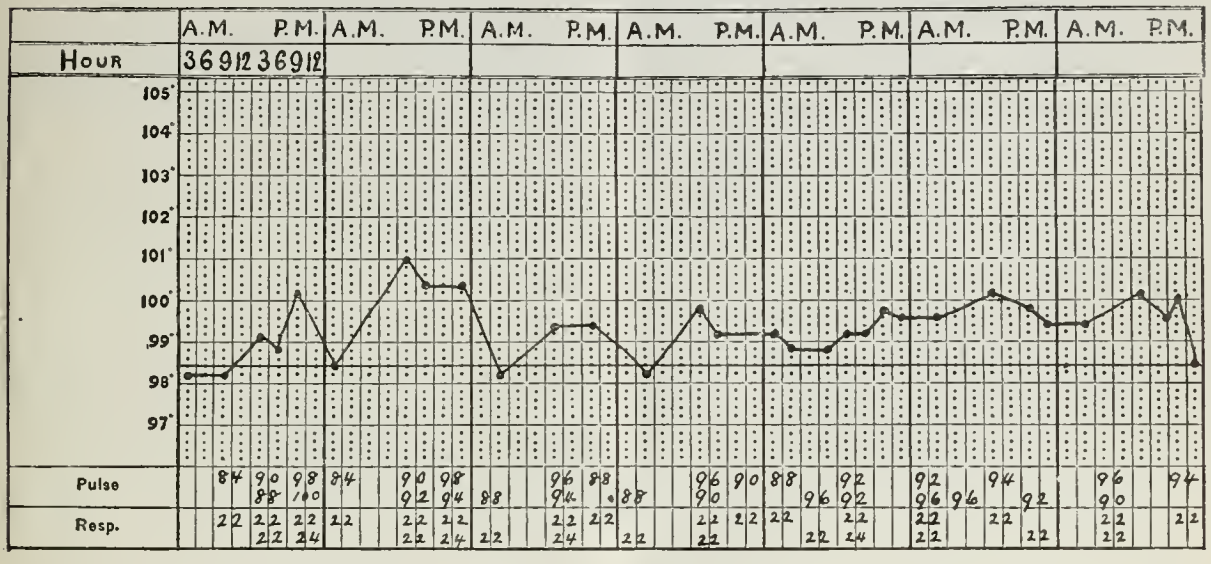
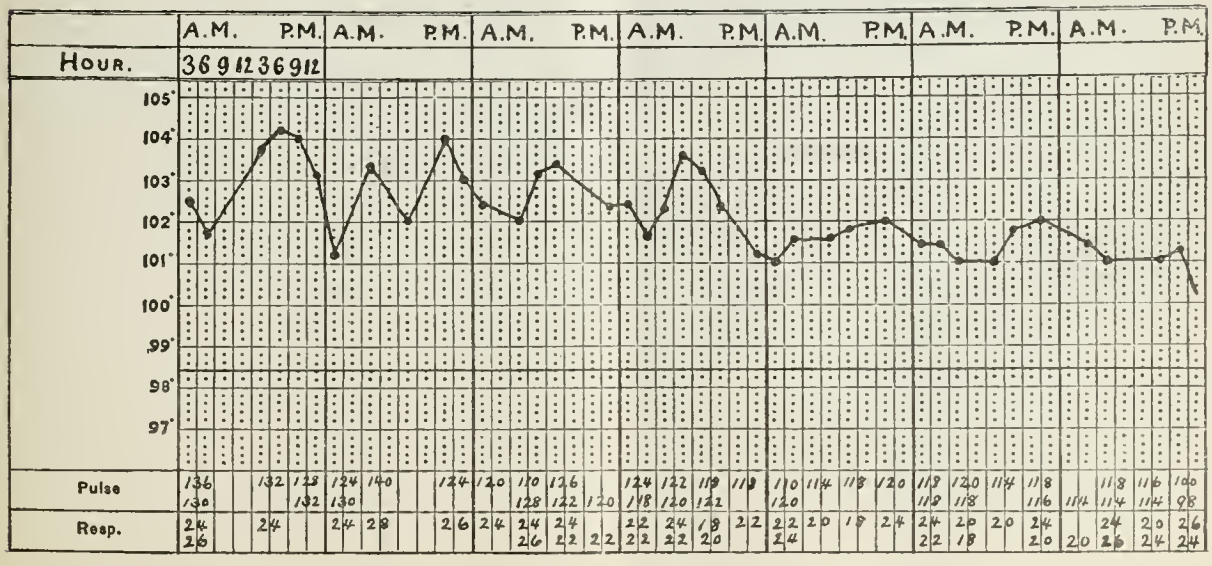


The author's case of scarlatina, with pseudomembranous (necrotic) patches on pharynx and tonsils.

CHART 3.—CASE II. FIRST WEEK AFTER SERUM TREATMENT.



Scarlatina maligna; extensive necrotic patches in the pharynx—both tonsils—with enlarged lymphatic glands.

had marked evidences of rickets. Carious teeth, Harrison's grove, and the funnel-shaped depression of the thorax is well marked. Her present illness began with vomiting and a temperature of 104°F. An exanthematous rash covered the entire body. Several membranous patches were plainly seen on the pharynx and tonsils. A culture taken showed the absence of Klebs-Loeffler bacilli. The glands of the neck were enlarged. A diagnosis of scarlet fever was made. Owing to the weakened state of the child, sepsis was feared, and hence I injected 20 c.c. of Aronson's antistreptococcus serum on February 15, 1903.

The usual aseptic method was thoroughly carried out to avoid local infection. The child's condition improved gradually and continuously. The most marked effect in this case was apparent, first, in the reduction of the temperature by lysis, and, secondly, in the gradual melting away of the pseudomembranes (scarlatinal necrosis).

At the time of writing (it is now the commencement of the third week) there *has been no disturbance nor complication*. The kidneys are active. There is no evidence of nephritis. Daily examinations of the urine have been made. As this child has rickets and is in a subnormal condition, I would not have been disappointed to find some toxic disturbances. I therefore feel inclined to give the serum the credit for this convalescence. Desquamation appeared about the fifth day after the injection.

Case II.—Hannah S., eight years old, was first seen by me February 20, in consultation with Dr. L. Kohn. The history given me by Dr. Kohn was that the child had been sick three days with a temperature of 104°F. the day previous and 104⅕° F. to-day. The pulse was weak and rapid. Large necrotic patches covered the entire surface of the pharynx, tonsils, and uvula. There was a marked fetor of breath. A very intense eruption covered the entire body. There was loss of appetite and a general apathetic condition. At the time of the injection of the serum, the following condition was noted: Temperature, 104⅕° F; pulse, 158; respiration, 26.

Owing to the severe general infection, I decided to give an injection of 20 c.c. of antistreptococcus serum.

On February 23 I saw the case a second time with Dr. Kohn and noted the entire disappearance of the necrotic patches in the throat. This condition is identical with that noted in Case I.

Dr. Kohn told me that this condition was already apparent on the third day after the serum injection.

The deductions after Baginsky's experience with this new serum were that "no secondary ill effects were noticed." The fever, even in severe forms of the disease declined steadily and continuously without interruption by complications.

Baginsky reported a series of observations, and demonstrated fever charts showing the gradual decline after comparatively small doses of serum. In some instances, two, rarely three doses of 20 c.c. each caused the gradual decline of the disease.

All in all, Baginsky maintains that with the exception of "serum rashes," there are no disagreeable effects from this new serum. Great care should be exercised in judging this new serum from a small, although a successful, series of cases.

The specific action of antitoxin in diphtheria is far greater comparatively than the action attained from the use of this antistreptococcus serum.

It is too soon to formulate definite conclusions based on an experience of two cases. The clinical results were certainly striking. The effect of the serum on the temperature shows that it did inhibit bacterial products. Another interesting observation in both cases is the disappearance—*almost melting* away—of the necrotic membranes after the fourth day. The temperature came down gradually by lysis. There was no crisis which could be distinctly noted, although Case I showed a marked antithermic result of the injection. The glands of the neck in both cases were swollen and subsided with the disappearance of the throat manifestations. The vital point consisted in a strengthening diet in addition to strict hygiene.

Thus I feel warranted in indorsing the view expressed by Baginsky, advocating the use of this new serum in the treatment of scarlet fever.

Kidney Complications in Æstivo-Autumnal Fever.—Ira R. Bartle reports cases of nephritis directly referable to attacks of malaria. So much have kidney complications in connection with this disease forced themselves on his notice, that he now never treats a case of even simple malaria without at least an every other-day examination of the urine, and he is satisfied that this precaution has saved the lives of at least a half-dozen patients. The greater the number of crescents and flagellated parasites present in the blood, and the more free pigment, the more does he deem necessary the daily microscopic examination of the urine, for with an excess of malarial infection, there is an excess of toxins producing inflammatory changes, or later, granular degenerative changes in the interstices of all glandular elements of the body, and especially the excreting organs. In the author's experience, blackwater fever has followed the administration of quinine in three instances of this complicating nephritis, with death in two, hence he follows the rule of using the remedy with extreme caution in cases of over five or six days' standing, when the infection is virulent, and follows the treatment used by the practitioners in the Yazoo and Red River Valleys in cases of pernicious malaria—namely, the use of hyposulphite of soda in ten to twelve-grain doses.—*Memphis Medical Monthly.*

The Treatment of Traumatic Gangrene of the Extremities.—Van Buren Knott recommends the following procedure. Being confronted with a case of traumatic gangrene of an extremity, estimate as exactly as possible the line between the deceased and healthy soft parts, and having first, under anæsthesia, made a most careful and complete disinfection and cleansing of the skin, puncturing all bullæ and removing all discharges, envelop the gangrenous area in a sterile towel up to the line selected, and at this point make a circular amputation, cutting through soft tissues and bone at the same level. Ligate carefully all bleeding points, including none of the perivascular tissue in the bite of either the forceps or the ligature. Leave the wound absolutely open, not introducing a single suture, and apply moist dressings of gauze saturated with salt solution, these dressings to be changed from two to four times in twenty-four hours. After seven to ten days, if the wound is perfectly clean and the condition of the patient favorable, the classical circular amputation may be made by dissecting up the flap already outlined and sawing the bone at the proper level. The author has in four cases had the best of results by this method. He enumerates its advantages as compared with the old method.—*The Railway Surgeon.*

New York, March 7, 1903.

ATTACK ON TENEMENT-HOUSE REFORM.

OWING chiefly to the efforts of the New York Charity Organization Society, laws were recently enacted by the State Legislature whereby tenement-house builders were compelled to conform to certain conditions in the erection of such structures in New York City. Tenement buildings under the new regulations have to be properly ventilated and efficiently lighted. In short, the dwellings of the poor must, in some degree, be fit for human habitation.

Senator Marshall and Assemblyman Dale have just introduced bills, now pending before the Cities Committee of the Legislature, which if passed will sweep away not only the reforms accomplished in recent years, but many of the alterations for the better which have been brought about in the past forty years. According to a pamphlet published on the matter, the bills would have the following effects:

They change the definition of a tenement-house so as to exempt from the operation of the law all buildings which contain less than five families. This would mean that more than 25,000 buildings would be left without any law at all, and without any supervision in regard to sanitary conditions, and without means of escape in case of fire, and prostitutes could ply their business in such houses without fear of being disturbed.

These bills would permit the erection of new four-story tenement-houses, containing as many as sixteen families, with wooden stairs, wooden floors in the public halls, and wooden partitions enclosing the public halls, and with the cellar stairs inside the house directly underneath the main stairs, making a continuous flue in case of fire, instead of having fireproof stairs, fireproof floors in the halls, and the halls enclosed entirely with brick walls, with the cellar stairs outside of the building, and no opening between the cellar and the first story. They would permit 75 per cent. of the lot to be covered in new buildings, instead of 70 per cent., thus diminishing the amount of space left for light and air. They would permit once more, in new houses, the construction of the old, dark, unventilated air-shaft, with all the sanitary, moral, and social evils that it produces, and in new four-story buildings public halls and stairs without any windows to the outer air whatsoever.

With respect to the old buildings, the bills would do away with all the improvements introduced and would leave the old houses as they are and would repeal nearly every section of the law which requires any alteration in an old house which costs money.

The attempt to repeal the present tenement-house legislation and to revert to the old order of things is dictated solely by interested motives. The New York Academy of Medicine has recently passed the following resolutions:

"*Whereas*, Strenuous efforts are being made to induce the Legislature to utterly undo the great advances made in recent years in tenement-house reform and sanitation, and to prevent the permanent carrying into effect the great improvements in the construction and management of tenement-houses in New York and Buffalo, which have been made possible by the recent Tenement-house law, and

"*Whereas*, Pulmonary tuberculosis is practically epidemic in the city of New York, there being eight thousand deaths and twenty thousand cases annually, and

"*Whereas*, The lack of light and air in the rooms of the great masses of the people is one of the most potent causes in increasing the prevalence of this and other communicable diseases, and constitute serious menaces to health and morality,

"*Be it resolved*, That the New York Academy of Medicine deplores any weakening of the present tenement-house laws, and urgently requests the Legislature to permit no changes to be made that will in any way decrease the amount of light and air available for the people living in such houses, or in any way take a backward step in regard to their sanitary condition."

The pressure of public opinion will—it may be hoped—be exerted to such an extent that the Governor and his advisors will be guided by the advice of the medical profession and sanitarians rather than allow themselves to be persuaded into an action harmful to the whole community, merely to satisfy a body of men solely actuated by a policy of greed.

As a matter of fact, the law with regard to tenement-houses instead of being weakened should be made much stricter. The increase of tuberculosis alone is a sufficient cause for steps in this direction. If the bills before the Legislature are passed, a further increase in consumption and other communicable diseases may be anticipated.

INFECTIVITY OF TUBERCULOSIS.

SIR HUGH R. BEEVOR, M.D., F.R.C.P., gave an address a few weeks ago in England in which he delivered himself of some eminently sage remarks with regard to the infectiousness of tuberculosis.

It has become almost an article of faith that tuberculosis is infectious to a very considerable degree, and many physicians spread the doctrine that it is extremely dangerous to live in the vicinity of those suffering from the disease. The menace to public health afforded by the consumptive dwelling among his sound fellow men has been probably exaggerated. Of course it would be much better for all concerned if phthisical subjects could be removed to a locality where they could have plenty of fresh pure air, and the diet most suitable to their condition, but, failing this, there is no need to create

a panic concerning their association with other persons.

Sir Hugh Beevor, speaking on the matter, said: "The term 'infection' is too loose a term to apply to both measles and tuberculosis. When its use does damage to the workman's prospects, it is perpetrating an injustice upon him. 'Sub-infectious' is a more proper term to employ in public health."

The author, after alluding to the poor results obtained by the isolating of infective fevers in hospitals for fever, says that "those who rank tubercle as most highly infectious must seriously doubt if it is a right policy to apply such a system to tubercle. He then ends his paper with these words: "I earnestly hope that the medical profession at large will not encourage the public to avoid their tuberculous fellow creatures. Such a course will not, in my opinion, diminish the amount of tubercle. It will, however, infallibly swell the ranks of the unemployed, it will depress the phthisical wage-earner's spirits, it will empty his pockets, and ultimately, by want and distress, reduce his family to that condition of low vitality which the tubercle bacillus requires for a successful invasion."

The wisest manner of regarding tuberculosis, after all, may be to look at it not as a highly infectious disease, but as communicable under certain conditions of receptivity, and as requiring only reasonable precautionary measures to prevent its spread.

It is not difficult to understand that much of the present scare concerning the communicability of tuberculosis has been the result of over-zealous efforts on the part of health boards to magnify their functions and increase public patronage. While this may be natural, under the circumstances, reasonable discretion should be used in not attempting to prove too much for the bacteriological as against the purely clinical side of the question. In the determination to kill the bacillus at all hazards we may lose sight of the patient. What is more needed now than extra appropriations for health board laboratories are greater efforts in improving the sanitary conditions of the tenement districts, thus rendering the soil of disease unfit for the seed. There is, of course, no argument against destroying tuberculous sputum and instituting proper sanitary precautions against the possible spread of any disease, but the tubercle bacillus is not the sole factor in the great problem of disease prevention.

THE GERMAN MEDICAL CURRICULUM.

Within the past fifteen years there has been much discussion in Germany as to the requirements for the right to practice medicine. After a thorough consideration of the matter by the universities and principal medical authorities of the country, a decision was come to, and the new regulation went into effect on the 20th of May, 1901.

The German methods of training, and testing by examination the knowledge gained by the student, are as uncompromisingly severe in the sphere of medical as in the other branches of education. Slipshod ways are an abomination to the disciplined and painstaking Teuton, and it may be confidently asserted that a man who has graduated in medicine in Germany knows his work at any rate by rote—as well if not better than the medical graduate of any other country. Only two examinations are required, but before going in for the first, candidates must present the certificate of a gymnasium or a real-gymnasium, and must have spent at least five semesters in medical study in one or more of the universities. This examination includes anatomy, physiology, physics, chemistry, zoology, and botany.

The second examination cannot be taken until ten semesters, including the half year of military service, have been passed in the study of medicine. This examination includes general pathology and pathologic anatomy, medicine and surgery, psychiatry and hygiene. The course throughout is severe and searching, and the latter examination is a good test of a man's practical knowledge.

After all this time has been spent in medical study, and after the two examinations have been passed, the successful candidate is not yet allowed to practise, but has to spend a year in hospital. The institution of this "practical year" is the most notable feature of the reforms introduced into the German system of medical education. The candidate has to spend the time in a university clinic, a university polyclinic, or a specially designated hospital may be selected, and is under the supervision and instruction of a director, a third of the year or more being devoted to internal diseases. The would-be medical man has to convince the authorities that he has increased his medical knowledge and ability and must show a sufficient understanding of the tasks and duties of the medical profession. If he fails in accomplishing this, he is compelled to continue for a period to be decided by the authorities. When he has successfully passed through the ordeal, and has furnished testimonials of good moral character, and has exhibited certificates showing that he has attended at least two public vaccination and revaccination periods, he is given the license to practise medicine in any part of the German Empire.

Whether the medical curriculum of most of the European countries is unnecessarily long and severe is a disputed point with Americans. There is little doubt, however, that in many States of this country the medical course is too short. The tendency on the other side of the Atlantic has been of late to lengthen the time of medical education and to make the examinations more severe. Even in Great Britain, it requires five years of medical training before a man can become qualified, and, as in Germany, the last year is taken up with practical work. Perhaps a native of this country would not care to spend so much time in mastering the details of the medical profession, regarding the matter from a material point of view.

An infusion of the German spirit of thoroughness in medical training might not, however, be amiss in many of the American medical schools.

Schleich's Methods for the Treatment of Wounds.

Dr. Philipp Bockenheimer gives (in No. 344 of the *Sammlung klinischer Vorträge*, 1902) an extended report on his apparently careful studies of the methods recommended by Schleich for the treatment of wounds. Since his introduction of glutol serum in 1894, Schleich has maintained that he no longer had progressive suppuration, and Bockenheimer considers that Schleich's acquisition of adherents in

various quarters has been not a little due to the enthusiasm with which, in his book, "Neue Methoden der Wundbehandlung" (Berlin, 1900), he points out his new ways of handling wounds and their brilliant results. Schleich's theory that the ideal dressing would be one which is aseptic and is like in kind to the normal, plastic, intermediary substance (composed of serum, fibrin, and cellular substance), in which healing takes place in wounds by organization, Bockenheimer endorses. Believing that he has found this, Schleich recommends three substances, pulvis serosus, glutol, and glutol serum, the last a combination of the other two. In Bockenheimer's hands, however, all three either failed signally in practice, or where, exceptionally, one succeeded other ordinary methods did equally well as regards the direct effects on the wound, and were, besides, much more convenient. Schleich's methods were very much more costly (which, considering that they offered no compensating advantage in the way of shortening the time of healing, or of greater ease in manipulation, was an important consideration), and were, moreover, very difficult for a beginner to learn, and even for a practiced dresser were hard to carry out.

All three powders formed, when dusted over a wound, a closely-adherent scab, which, being almost impervious, retained under it the accumulating secretion, thereby necessitating frequent removals and renewals. The condition of the wound was also not open to inspection. The adhesiveness of the scab necessitated the giving of much more time to the dressing, and almost always resulted in the tearing away of bits of new-formed tissue, thus causing bleeding and retarding healing. In small aseptic wounds, with little or no secretion, the powders did well, but no better than the usual methods. In suppurating cavities it was impossible to get the powders into all the pockets, and they formed hard cakes, that could not be gotten out entirely, which resulted in retention in the wound of the decomposing secretion, which saturated them. Indeed it was found possible to prolong suppuration at will by the glutol serum treatment. Used in gauze, the powders simply acted to clog the gauze and hinder its power of absorbing the secretions. In phlegmonous cases the powders were positively dangerous by their retention of infected secretions. Bockenheimer also tried Schleich's pastes, pasta serosa, and pasta peptonata. He found them, however, either of no value, or of no greater value than the more convenient and cheaper methods in ordinary use. The preparations are, besides, difficult to keep. The pastes get dry, and have to be re-prepared before use, and, with constant opening, it is simply impossible to keep the powders aseptic. Bockenheimer concludes that Schleich's methods can never be of general utility, and that they will never find a permanent place in our treatment of wounds.

Rigor Mortis in the Fœtus.

In the *Sammlung klinischer Vorträge* (No. 343; 1902), Ludwig Seitz gives an exhaustive critique of this subject, supporting his conclusions with abundant evidence. In the adult rigor mortis bears the closest relation to normal muscle activity. The results of the latter are the production of lactic and carbonic acids. Probably the only differences between the two conditions lies in the non-removal, in the dead body, of the acids from the muscle. At any rate, their accumulation is the cause of rigor mortis by the production of coagulation of the myosin. This involves shortening, and the stiffness is due to simultaneous contraction of opposed groups. Rigor mortis is hastened by previous muscular exertion, and it can be produced by the injection of acids and chloroform. It has two stages, a preliminary waxy rigidity, and the well-established stiffness. Turning to fetal life, the best-known textbooks of the day, physiological and medicolegal, state that rigor mortis does not occur before the seventh month, which is, beyond question, erroneous. The author gives eleven cases observed by him of fœtuses in more or less general rigor mortis, the length ranging from 18 to 36 cm., the weights from 130 to 1,800 grams; the temperatures from 1 to 8° C.; and the time of examination (where known) from seven to forty-eight hours after death. The rigidity was true rigor mortis, and not a desiccation effect, as it occurred equally when the fœtuses were wrapped in wet cloths and was present in one fœtus still in the amnion. As regards fetal rigor mortis in utero (or at the moment of delivery), since 1894 twenty cases have been reported by three observers. The author adds four of his own, making twenty-four in all. But why do we only know these few cases? The chief reason is that rigor mortis is passed through, to the subsequent relaxation, in utero. It could occur there, inasmuch as, though the subsequent relaxation is generally regarded as a decomposition effect, L. Herrmann has shown that it can occur when decomposition is excluded, the continued action of the acids present leading to the formation of acid albumin. That it actually is passed through there is, moreover, indicated by those cases in which the recently dead fœtus (in which no maceration is visible) is born relaxed, and is incapable of passing into rigor mortis. Of this the author gives a case in which, during forty-eight hours, no rigor mortis set in, and the injection of acids and chloroform failed to bring it about. Further, when the child dies during birth, the length of time after death is, in an average parturition, not sufficient for rigor mortis to develop, and after extracting a dead child, the accoucheur having much else to engross his attention, usually pays no further attention to it. Besides rigor mortis, especially in its first stage, can be broken up by the movements impressed upon the child during parturition, especially if manipulative assistance is given. And actual cases are cited in which unusual difficulties in operative procedures have been reported as due to unusual stiffness of the fœtus; in which, at birth, rigor mortis was present everywhere except just in the parts manipulated, and in which no one of a number of physicians had noticed anything peculiar in a child in which, when extracted, the arms were stiff, and five minutes later rigor mortis was thoroughly established. The second case shows that, as might be expected, in its second stage also, rigor mortis in the fœtus can be broken up during parturition.

In at least one case fetal rigor mortis has assumed medicolegal importance (*British Medical Journal*, 1874, p. 772): a woman was acquitted of murder on expert testimony that, as rigor mortis had occurred, the child must have been born alive.

A Patent Medicine Bill.

A bill has been introduced into the Assembly of the State of New York to prevent frauds in the advertisement and sale of patent medicines, medicinal foods and beverages and merchandise. The act in question provides that no advertisements of any patent medicine or its like shall be circulated in the State of New York, unless the same shall previously have been examined, approved and certified by the local Board of Health, with regard to the truth of the representations made as to its medicinal

properties; and, further, that the person alleged to have made a representation shall verify the fact of having done so under oath. Every certificate thus granted to be valid for one year only, and every person, corporation or association violating any of the above provisions to be liable to a heavy fine. This bill is comprehensive and drastic, and will be deemed by those engaged in the manufacture of proprietary medicines as decidedly too sweeping in its provisions. Indeed, it is declared that the enactment of such a measure would destroy the business of makers of patent medicines. There is, however, no doubt that many of the highly lauded so-called specifics which are widely sold are useless, when not deleterious. On the other hand, there are proprietary medicines which do good. Those who manufacture the latter should not fear the examination of their products by an unprejudiced body of men, while those who attempt to foist spurious articles upon a gullible public will be justly driven out of business.

New Methods of Medical Treatment.

In the report of the recent Egyptian Congress, sent by our special correspondent, mention was made of the novel therapeutical suggestions contained in the address of Professor Bouchard. He suggested that, in both local diseases and in general diseases which are localized, if a general drug treatment exercising a specific cure could be replaced by the confinement of the remedy to the diseased area by direct injection, we might attain results hitherto unreached in the cure of disease. Acting on this idea, he has found acute articular rheumatism disappearing after the injection *in situ* of extremely small quantities of sodium salicylate. In some instances the joints were rapidly cured by the injection of half a grain, and he found it exceptional that a synovitis did not clear up after the use of from two to three grains dissolved in a drachm of water.

In a translation of the address, published in the *Lancet* of February 7, 1903, a number of the results obtained by this method are recorded. Several times injection into the painful thoracic muscles had stopped an early pleurisy, and in rheumatic pericarditis he has seen an injection of one and one-half grains lower the fever from 102° to 100°; then a second injection was made, and in three days friction sounds had disappeared. In endocarditis he failed and said that he could not pretend to attain the success of Moritz Benedikt, who, with a solution of carbolic acid (2 per cent.), had seen cardiac affections disappear without leaving any trace behind. He has, however, cured cases of painful muscular contraction of the adductors of the thigh, and has seen good results in neuritis, such as sciatica. In these cases he injected in the neighborhood of the diseased tissues, not in the tendons or nerves. In the same way, when it is a question of inflammation of the serous linings of joints or of internal organs, he has not introduced the drug into the affected cavities, but into the neighboring tissues as near as possible to them.

In tabes dorsalis the salicylate injections failed. Iodide injections, thirty minims of a three-per-cent. solution permanently eased the pains in some cases of ataxia. The combination of mercuric iodide with potassic iodide benefited some cases rebellious to the latter alone.

These results led him to try a similar therapy in a case of ulcerating gumma of the back in which the usual methods of administering mercury and the iodide had failed to produce any result. He then injected one grain of the iodide near the gumma, which promptly healed. In another case, after unsuccessful general treatment and its being relinquished, the gumma disappeared under the influence of three injections each of one grain of iodide of potassium. A woman suffering from severe syphilis had on several parts of her body deeply ulcerating condylomata. He gave her mercury and iodide in the ordinary way, but at the end of a month her stomach could no longer take the iodide; the injections of benzoate, and later of cyanide of mercury, produced lumps of the size of a nut, and her general condition was no better. He therefore stopped the former treatment and experimented on some of the tumors by injecting into them iodide of potassium and biniodide of mercury. In three days a condyloma, into the base of which he had made two injections was cured. Another ulceration was healed after six injections. During this time the other condylomata were not treated at all and showed no improvement. The patient's weakness increased and her hair again began to fall out.

Bouchard admits that it is not quite certain how these infinitesimal doses produce their action. Local treatment, because it is local, brings the drug into the affected area and makes it antiseptic without a general toxic diffusion in the whole body. Concerning the question in general, he says that without neglecting general treatment local means are becoming more and more employed, sometimes by setting up an antiseptic action, sometimes by awakening antitoxic processes by which methods the treatment becomes a cure.

Establishment of a Laboratory of Criminology.

Mr. Arthur McDonald, the well-known authority on criminology, requested some time ago that the Warren County Bar Association should pass a resolution recommending the establishment by Congress of a laboratory in the Department of Justice, for the study of the criminal, pauper and defective classes. Accordingly, a committee of this association was formed and recently has sent in a report on the matter through its chairman, Mr. Edward Lindsey, which report has been adopted as that of the committee to the association. The report gives a good sketch of the science of anthropology, and concedes that investigations into the subject are of high value and importance, but fails to perceive the direct relation of criminology to jurisprudence. Mr. Lindsey states his opinions on the matter as follows: "In apportioning its punishments the criminal law cannot look to the deterrent effect upon one individual, but upon every individual in the State. The science of criminology should be cultivated for the knowledge that may be obtained, but it should be pursued as a scientific investigation and not as a branch of jurisprudence, with which it has no direct relation." The passage of the following resolution by the association was recommended by the committee: "*Whereas*, This association has been requested by Mr. Arthur McDonald to pass a resolution favoring the establishment in the Department of Justice, at Washington, of a laboratory for the study of the criminal, pauper, and defective classes; and *Whereas*, While recognizing the usefulness of the study of the aforesaid classes by exact methods, we are not, as lawyers, concerned with the advisability of its being undertaken by the Government, and we believe that it has no direct relation to jurisprudence, to the law, or to the administration thereof; Therefore be it *Resolved*, That without expressing any opinion as to the advisability of establishing the aforesaid laboratory, we most earnestly recommend that it be not established in

the Department of Justice, where, in our opinion, it would be foreign and conflicting with the aims, subject-matter, and method of the Department."

From a purely legal and educational standpoint the scientific study of the criminal or of other abnormal classes may not be desirable, but at the same time, judging from results reported from some European countries, the study of man conducted upon scientific lines has been useful and successful.

A Chance for Wholesome Legislation.

It has been suggested that the passage of the Nurses' bill, introduced this week in the New York State Legislature, should make it possible in another year to settle the question of midwives and their legal recognition. Why wait another year? We would suggest a "rider" to the Nurses' bill as follows:

On and after September 1, 1903, no person, unless previously registered as a midwife in the Health Office of the city in which she resides or in the city nearest to her residence, or in the County Clerk's Office, said registration bearing with it the attest of two duly licensed physicians vouching for the good moral character of such midwife and testifying to the knowledge of said physicians that the said midwife has to their knowledge attended at least five cases of midwifery, each such case to be enumerated and verified by the Health Officer from the records in the health department where such services as midwife were rendered, shall be permitted to practise as a midwife or to advertise herself as a midwife unless holding the title of Registered Nurse, as provided for in this article. All such registered nurses desiring to engage in the practice of midwifery shall register their names in a book kept for that purpose in the County Clerk's Office, for which said County Clerk shall charge a fee not greater than one dollar. Nothing in this act shall be construed as giving said registered nurses or midwifes any of the rights or privileges of a licensed practitioner of medicine excepting as to exercising their energies in caring for the pregnant woman during the progress of a normal labor. This act shall not apply to licensed practitioners of medicine in the State of New York.

We would suggest the above, possibly modified in verbiage here and there, to the counsel and legislative committees of the various State societies. The midwifery evil is a condition not a theory, and every day of delay in correcting or mitigating the evil is an added indictment of criminal neglect against the medical profession. Almost one-half the cases of birth in New York City are, and have been for years, presided over by uneducated midwives. The resultant evils, too often pictured in daily practice to need more than passing mention here, are so great and so numerous as to call for legislative interference. "Now is the accepted hour."

A Contemporary's Fears Allayed.—A stirring editorial protest appeared recently in the *Lancet* against the establishment in London of American "quick lunch" places, and physicians were adjured to warn their patients against the pernicious habit of eating on the run. One of the promoters of the scheme, moved by this published appeal, has now gone to the trouble of informing the perturbed editors that "quick lunch" is short for quickly-served lunch, and does not at all imply quickly-eaten lunch. Here is an opportunity for another and commendatory leader in which physicians will be urged to drive their patients to the "quick lunch" places. For surely, if the lunch hour is at all restricted, the more rapidly the luncheon is served the more leisurely may it be eaten.

News of the Week.

The Fourteenth International Medical Congress.—The social side of the Madrid Congress will not be neglected. It is announced that the King and the Queen Mother will give a garden party and a general reception at the palace, and the municipality is organizing a general fête with possibly a special play at one of the theaters. There will also be a bull fight in honor of the congress, and there are to be a number of special excursions organized by the various sections. The Spanish railways announce that at Madrid, from April 3 to May 24, special tickets will be issued to members of the congress who may wish to visit Granada and other cities of Southern Spain; these tickets may be had at the same reduction of 50 per cent. as is allowed on round-trip tickets from other cities of France and Spain to Madrid.

A New Bellevue Hospital.—The Board of Estimate and Apportionment of this city has taken action looking to the construction of a number of new public buildings, among them a new Bellevue hospital, at a cost of $3,000,000, and new buildings for Fordham Hospital to cost $500,000. In addition to these hospitals, the Board will authorize the construction of eighteen new free baths in Manhattan and three in Brooklyn, to cost $90,000 each; one very large public bath and laundry at Twenty-third street and East River, Manhattan, to cost $200,000, eighteen public comfort stations in Manhattan, to cost $540,000, and six public comfort stations in Brooklyn, to cost $25,000 each.

New Harvard Medical School Buildings.—It is announced that work will begin soon on the proposed Harvard medical school buildings in the Back Bay Fens. The architects are completing the plans, several changes having been found necessary since the project was first planned for. If there are no serious delays in securing the necessary building material, it is believed that the buildings will be completed in about a year. The work will be pushed forward with all possible rapidity as soon as an actual start has been made. The proposed buildings will occupy a twenty-six acre lot. The cost of the entire group of buildings is estimated at more than $2,000,000, of which J. P. Morgan contributed one-half. The medical school will use five of the buildings, the dental school one, and there will be a large power-house. It is expected that the original plan will be carried out, that of having the five buildings surround three sides of an open court, 520 by 215 feet in dimension, the entrance to which will be through a gate from Longwood avenue.

Tent Life for Tuberculosis on Blackwell's Island.—It is proposed to move the consumptive patients now under the care of the Commissioners of Charities at the Kings County Hospital to Blackwell's Island and house them in tents.

Bellevue Nurses Unjustly Accused.—The charges recently made against certain of the Bellevue Hospital nurses that they had maltreated a patient in the alcoholic ward, have been dismissed at the request of the district attorney, who says that the charges were unfounded, and that the patient was in no way maltreated.

Public Moneys for Private Hospitals.—A bill has been introduced into the Assembly of this State, making it lawful for the town board of any town in which the yearly assessed valuation of real estate is over $10,000,000 to vote any sum of money not exceeding one thousand dollars in any year for the maintenance of a hospital located in said town, which is supported, in part, by charity, and which

gives medical aid and treatment and surgical advice to poor patients without pay.

Trouble in the Jersey City Hospital.—There has been war for some time in the City Hospital, Jersey City, between the nurses and the house surgeon, and this culminated last week in the presentation of an ultimatum by the nurses. They notified the warden that they would resign in a body unless the house surgeon was removed, and this threat won them the first battle, as the house surgeon has been suspended pending an investigation of the complaints of his actions made by the nurses.

A Legacy to the New York Hospital.—Mrs. James H. Banker, widow of a former director of the New York Hospital, died a short time ago, leaving by will $25,000 to the society of the New York Hospital with which to build on the new grounds of the asylum in White Plains a villa for the accommodation of insane patients, and to bear the name and be in memory of her deceased husband.

Philadelphia Neurological Society.—At a stated meeting, held February 24, Dr. Chas. Lewis Allen read a paper entitled "The Changes Found in the Central Nervous System in a Case of Rabies with Symptoms of Acute Mania." He related the case of a man bitten by a dog supposed to be rabid, and who became greatly alarmed and gave himself up to alcoholic excess. Death resulted and post-mortem examination revealed the lesions of meningomyeloencephalitis. The changes in the Gasserian and the spinal ganglia described as characteristic were but slightly marked. Inoculation of lower animals with some of the nervous tissue resulted in the development of paralysis of the hind legs and other symptoms characteristic of rabies. Dr. Harvey Cushing of Baltimore read a paper entitled "The Surgical Treatment of Facial Paralysis by Means of Anastomosis." He reported the case of a man in whom the facial nerve was severed by a bullet directed with suicidal intent against the mastoid region, but penetrating only to the base of the skull. After an interval of about six weeks the peripheral extremity of the divided nerve and also the neighboring spinal accessory nerve were exposed, the latter divided and the proximal extremity of the spinal accessory united by suture with the distal extremity of the facial. As time went on, there was marked restoration of motor power and of electric reactions on the previously paralyzed side of the face, although for a time there was some degree of association in the movements of the muscles supplied by the spinal accessory and those supplied by the facial. Dr. W. W. Kenn read a paper entitled "Anastomosis of the Seventh and the Spinal Accessory Nerves for Traumatic Facial Palsy." The patient was a man who had been struck on one side of the face by a beer-bottle, with resulting division of the branches of the facial nerve. With some difficulty a portion of the spinal accessory nerve was united by suture to a portion of the facial nerve upon the same side, but the patient was indifferent to the result, and hence the outcome was unknown, although it was feared that it would not be successful. Dr. Alfred Gordon read a paper entitled "Remarks on Primary Neurotic Atrophy (Charcot-Marie-Hoffman type), with the Report of a Case in Which There Was Excessive Indulgence in Tea and Coffee." He also exhibited the patient, who was an adult male, presenting weakness and wasting in the lower extremities, more marked on the right, with fibrillary twitching, foot-drop, diminution in electric irritability, abolition of knee-jerks, unsteadiness of station, some wasting of the intrinsic muscles of the hands, slight optic atrophy, and nystagmus. The case was considered one of mixed peripheral neuritis and chronic anterior poliomyelitis.

Philadelphia County Medical Society.—At a stated meeting, held February 25, Dr. L. J. Hammond reported a case illustrating the importance of operation in certain forms of facial paralysis. Dr. G. Betton Massey read a paper entitled "The Treatment of Cancer of the Rectum by Mercuric Cataphoresis." Dr. C. E. deM. Sajous read a communication entitled "The Ductless Glands as Organs of the First Importanee in Vital Functions, and Their Relationship to Disease and Therapeutics." He expressed the belief that the secretion of the adrenal glands is carried to the lungs, where it plays an important part in the process of oxygenation. The glands are supposed to be connected by nerves with the anterior pituitary body and controlled by the latter, which also regulates the amount of oxygen absorbed from the air. Disease-poisons that stimulate this body cause an increased in-take of oxygen, with increased combustion in the tissues and consequent destruction of the poison. Vulnerability to disease is due to deficient functional activity on the part of the pituitary body, with imperfect oxidation in the tissues and lowered vitality. The pituitary body is susceptible to the influence of various medicaments, and in this way the morbid effects of its deranged activity can be counteracted.

Columbus Hospital.—At a meeting of the Medical Board of the Columbus Hospital of New York, held on February 2, the following appointments were made: Dr. Farquhar Ferguson was transferred from visiting to consulting physician to the hospital; Dr. Frederick C. Keller was appointed attending physician, and Dr. Henry Hazen, attending physician in diseases of children.

Appendicitis Ruled Out.—Mr. Murray, editor of the New English Dictionary, has condemned the word "appendicitis," refusing it a place in the dictionary. His explanation of this action is that words ending in *itis* are not English, and therefore do not come within the scope of an English dictionary, unless they happen to be in English use, like "bronchitis." He does not condemn it because of its uncouthness and barbarity, as such, and would probably fire out even more rapidly the more legitimate word, "ecphyaditis," which some would-be purists have tried to substitute for it. "Appendicitis" is without doubt an offensive word, or was at first, but custom is giving it the right of citizenship, and the purists must yield. Mr. Murray should recall the unequal struggle of Dame Partington of Sidmouth with the waters of the Atlantic.

The Samuel D. Gross Prize of the Philadelphia Academy of Surgery.—The conditions of this prize of $1,200 are that it shall be awarded every five years to the writer of the best original essay, not exeeeding one hundred and fifty printed pages, octavo, in length, illustrative of some subject in Surgical Pathology or Surgical Practice, founded upon original investigations, the candidates for the prize to be American citizens. It is expressly stipulated that the competitor who receives the prize shall publish his essay in book form, and that he shall deposit one copy of the work in the Samuel D. Gross Library of the Philadelphia Academy of Surgery, and that on the title page it shall be stated that to the essay was awarded the Samuel D. Gross Prize of the Philadelphia Academy of Surgery. The essays, which must be written by a single author in the English language, should be sent to the Trustees of the Samuel D. Gross Prize of the Philadelphia Acad-

emy of Surgery, care of the College of Physicians, 219 S. Thirteenth Street, Philadelphia, on or before January 1, 1905. Each essay must be distinguished by a motto, and accompanied by a sealed envelope bearing the same motto, and containing the name and address of the writer. No envelope will be opened except that which accompanies the successful essay. The Committee will return the unsuccessful essays if reclaimed by their respective writers, or their agents, within one year. The Committee reserves the right to make no award if the essays submitted are not considered worthy of the prize. The trustees are Drs. John B. Roberts, William L. Rodman, and William J. Taylor.

Dr. Robert G. Le Conte has been appointed by Governor Pennypacker Surgeon-General of the National Guard of the State of Pennsylvania to succeed Dr. John V. Shoemaker.

Resignaton of Prof. George L. Peabody.—Dr. George L. Peabody, for seventeen years professor of Materia Medica and Therapeutics in the College of Physicians and Surgeons, has resigned in order to gain additional time for his private work.

Obituary Notes.—Dr. Alexander Stanley Hancock of this city died on February 28 of laryngeal tuberculosis. He was born in Derbyshire, England, sixty-five years ago, and went to Canada at the age of forty years. He was graduated in Medicine at Toronto, and for five years was surgeon to the Allan line of steamships. He then moved to Buffalo, and subsequently came to New York, where he practised for ten years, until illness compelled him to retire.

Dr. George Clarence Gage died last week at his residence in this city, at the age of fifty-two years. He was a graduate of the College of Physicians and Surgeons, Class of 1872. For some time he was assistant surgeon in the New York Eye and Ear Infirmary.

Dr. David A. Kappes died at Philadelphia on February 14, at the age of forty-four years, as a result of pneumonia following septicæmia. He was a graduate of Jefferson Medical College in the Class of 1884.

Dr. Cochran McClelland died at Philadelphia on February 16 at the age of fifty-nine years, as a result of pneumonia. He was graduated from Jefferson Medical College in 1873, and was for a time assistant in gynecology in that institution.

Dr. David M. Anderson died at Venetia, Pa., on February 16, at the age of sixth-five years, as a result of pneumonia. He was a graduate of the medical department of the University of Michigan in 1866, and he served as cadet assistant surgeon during the Civil War.

Obituary.

THEODORE GAILLARD THOMAS, M.D.,

NEW YORK.

With the death of Dr. T. Gaillard Thomas, which occurred suddenly from disease of the heart on Saturday, February 28, one of the most noted of the great New York physicians of a generation ago has passed away. Dr. Thomas was born on Edisto Island, S. C., November 21, 1832, and was educated in Charleston, graduating in medicine from the college of that city in 1852. Soon after graduation he came to New York and became a resident physician at the Emigrant Refuge Hospital on Ward's Island. Upon leaving that institution he went abroad with Dr. Cornelius Agnew and studied in various cities in Europe for eighteen months, at the end of which time he returned and started in practice in this city. In order to eke out the scanty income of a beginner in medicine he established a quiz class in obstetrics in partnership with Dr. Donagee. This quiz was especially for students of the New York University, but soon became so popular that students from other institutions flocked to it in great numbers. His success in this field was for him recognition from the faculty of the University and he was appointed in 1855 to succeed Dr. Bedford as lecturer on obstetrics. Here he remained eight years, going then to the College of Physicians and Surgeons to accept the professorship in obstetrics offered him by the faculty of that institution. This he retained until the new chair of gynecology was established when he was transferred to the latter. The same year he was appointed physician to the out-patient department of the Woman's Hospital, and ten years later was made attending surgeon to the same institution. He was one of the members of the first board of attending physicians to Roosevelt Hospital and served in the same capacity at various times at St. Luke's, Bellevue, the French Hospital, and the Nursery and Child's, and also at St. Mary's Hospital in Brooklyn

Early in his professional life Dr. Thomas had the good fortune to become associated with Dr. John T. Metcalfe, then the favorite physician of the wealthy class in New York, and his material success was immediate. His practice soon became very large, but his preference was for obstetrics and the diseases of women, and he devoted more and more of his time and study to those branches, especially the latter. His work on the "Diseases of Women," published in 1868, was the most complete and advanced treatise of the subject then in existence, and it soon attained a very large sale, establishing the reputation of its author once for all as one of the greatest authorities in gynecology in the world. The book went through seven editions in America, and was translated into five languages. This was his *magnum opus*, but he was for many years a frequent contributor to medical periodicals, both special and general. He was an honorary member of all the leading obstetrical and gynecological societies of Europe.

Dr. Thomas was a bold and skilful operator. In obstetrics he was an advocate of laparo-elytrotomy as a substitute for cæsarean section, and in gynecology his specialty, if so it might be called, was laparotomy, in which operation he had an enormous experience. As a clinical teacher and lecturer he was unrivaled in his day, though it is related of him that his first lecture at the New York University was a dismal failure; he was seized with stage fright, hesitated and stammered, forgot his subject, and finally gave it up and dismissed the class. He manfully returned the following day, began to speak quietly, and soon had his auditors spell-bound. As a diagnostician few could equal him. He seemed to seize at a glance the salient features of the case and to arrive by intuition at a true knowledge of the condition present. In private life he was most genial, beloved by patients and colleagues alike; a man of honor, of high culture, and of innate refinement, whom to know was an honor and an education. In November of last year a dinner was given to him in honor of his seventieth birthday, when some two hundred friends and admirers gathered to wish him all good things. That was the last time many of his friends saw him, for he went south for the winter to Thomasville where he was when the final summons came.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE KING'S HEALTH—HOSPITAL FUND—ROYAL MEDICAL BENEVOLENT COLLEGE — ST. BARTHOLOMEW'S WAR OFFICE ON NURSING—OBSTETRICAL SOCIETY; PRESIDENT'S ADDRESS—PUERPERAL INSANITY—GYNECOLOGICAL NURSES—THE ASYLUM FIRE, VERDICT—PROFESSOR CUNNINGHAM.

London, February 13, 1903.

The King progressed so rapidly that on Tuesday he returned to London. He had taken drives in Windsor Park on the previous Saturday and Monday.

Yesterday the Prince of Wales received a deputation from the Worshipful Company of Musicians, who presented him with £866 2s. for the King's Hospital Fund. This sum was realized by sales of Mr. Percy Godfrey's Coronation March, which was awarded the Company's Prize.

The Prince has consented to take the chair at the festival dinner of the Royal Medical Benevolent College, which was opened in 1855 by the late Prince Consort, accompanied by his present Majesty.

Yesterday a petition, signed by above six hundred citizens and residents, near St. Bartholomew's Hospital, was presented to the Court of Common Council praying that the corporation would take steps to prevent the removal of that charity to another site. The petition declared such removal would be a calamity to all dwellers in the city and all whose occupation brought them within its boundaries. That seems a rather strong statement although the facts adduced in its support cannot be gainsaid. It was said that the hospital is the only large general one within the city, that it is surrounded by markets, railways, the General Post Office, and many large establishments. It was further said that out of the thousands of patients relieved there many would be fatal but for its help. After some discussion the council decided to ask the Lord Mayor to lay the petition before the Mansion House Committee on the hospital.

Of late the War Office has been striving after a reputation for incubating schemes of "reorganization" which some of its irreverend critics call "tinkering." Buttons and boots having for the moment been insufficient to exhaust its reorganizing energies, the Royal Army Medical Corps has been taken in hand and a new scheme propounded. This is that the non-commissioned officers and men should be divided into four sections, viz., (1) Pursing, (2) cooking, (3) clerical, (4) general duty. To the last will be allotted hospital duties only indirectly connected with the care of the sick. Advancement to higher grades and promotion will be through Section 1, and an attempt will be made to render nursing more attractive by revised pay, etc. The Queen has expressed a wish that the best-conducted men nurses shall be admitted to H. M. nursing service, and a badge denoting this distinction is proposed for those who obtain it.

The President of the Obstetrical Society (Dr. Peter Horrocks) delivered his annual address on the 4th inst. He mentioned the changes in the society's laws by which legally qualified women became eligible for admission, and stated that ten had already joined the society. The rule permitting authors of papers to publish them in other journals than the *Transactions*, he said, had worked satisfactorily. The Pathological Committee had done excellent work, no less than fifty-nine specimens of more than average interest and importance being exhibited during the year. A brief notice of the papers read and the discussions following them was given, and the president then mentioned the Fellows who had died during the year. Of these his most interesting notice was that of Dr. Oldham, whose death at eighty-seven years of age I have previously mentioned with most of the others. Dr. Horrocks had obtained some notes of Dr. Oldham's career from Sir S. Wilks, who was a colleague, and from others. Dr. Oldham was one of the founders of the society, a V. P. from the first, president in its third year, and one of the trustees for above forty years. He was a very popular lecturer at Guys' Hospitals—"one of the best Guys' ever had." The president concluded by thanking the honorary secretaries, Drs. Herbert Spencer and Amand Routh, for the able assistance they had rendered him during his two years' presidency.

Is there such a disease as puerperal insanity? This question, followed by half a dozen others, was asked by Dr. Robert Jones by way of bringing on a discussion at the Obstetrical Society. His own views on various points concerning the disease were stated in a series of propositions drawn from his experience of 250 cases; of these 120 began during the actual puerperal period, eighty-three during lactation, and fifty-six during pregnancy. He estimated that insanity occurred in one out of 700 confinements, and that it was so characteristic as to amount to a nosological entity after delivery, but was far less definite during pregnancy or lactation. About 33 per cent. of the cases were in the first puerperism and came on suddenly. Insomnia and headache were early symptoms and should be a warning of danger. Prognosis was that recovery might occur in three months, but oftener took four or five. As to treatment, Dr. Jones said it was best at home when practicable, and comprised absolute rest and quiet; sleep must be procured and the patient watched to guard against sudden impulses to suicide or infanticide. A number of other points were mentioned, and Dr. Jones succeeded in eliciting a full discussion, of which I add some notes.

Sir John Williams commented on the peculiar condition of the nervous system during pregnancy, parturition, and the puerperal state.

Dr. Blandford said the earliest sign of danger was unquestionably loss of sleep, and this demanded the most careful watching and precautions against noise or any disturbance. Absolute quiet was necessary—no talking or even whispering in the room.

Dr. Herman said the main duty as to insanity was to prevent it, and for this food and sleep were necessary. He preferred alcohol in spite of obvious objections to morphia, chloral, or other hypnotics. He did not consider medical men were justified in discountenancing a projected marriage further than expressing their fears as to a possible or probable result.

Dr. Mercier did not think headache so important, but that the only trustworthy indications were sleeplessness and loss of appetite. He protested against the idea that home treatment could be satisfactory.

Dr. Champneys agreed with previous speakers as to the significance of sleeplessness. He also thought alcohol the best hypnotic in these cases. Mental distress in illegitimate pregnancy he did not think could be reckoned an important factor; it varied so much with the moral standard in different countries.

Dr. Andriezen estimated that mental disorder followed illegitimate births twice as often as legitimate.

Dr. Mott mentioned gangrene as an occasional sequelæ. He had seen a case in the county asylum which developed symmetrical gangrene of the feet. There was septic endometritis, and when this was treated the mental condition improved.

Dr. Percy Smith thought restlessness and confusion of thought the most important symptoms next to insomnia. There was no definite form of disorder characteristic of the disease; it might be delirious, confusional, maniacal, melancholic, stuporous, or delusional. Alienists often found a previous history of hysteria in cases admitted to asylums, and many of these were really mental attacks, euphemistically termed hysteria. Such patients ought not to marry.

Dr. E. W. White thought the estimate of 1 in 700 much too low and that probably 1 in 400 would be nearer. Many cases were treated at home, so that asylum statistics did not express the facts.

Dr. W. S. A. Griffith regarded with great suspicion cases of great fear on the part of a woman that she would become insane unless the pregnancy could be terminated; there were sometimes attempts to induce the doctor to procure abortion.

Dr. Tuke insisted on good feeding—artificial if necessary. He urged the danger of forming the alcohol habit.

Dr. Claye Shaw said mental disorder was often associated with sexual excitement at certain periods apart from pregnancy and even in both sexes. In acute mania, coming on soon after parturition, there was probably a connection between the mental and physical state, especially if the temperature rose.

Dr. A. Routh advocated the establishment of intermediate homes for treating these cases. The plan would avoid the stigma of the asylum, and friends would more readily agree to removal.

Dr. Horrocks said obstetricians saw these cases earlier than alienists. He thought refusal of food a more dangerous sign than sleeplessness.

The Gynecological Society is about to follow the bad example of its elder sister and rival—the Obstetrical. You know how the last trafficked in diplomas for midwives. The Gynecological now proposes to take nurses in hand and certify those she finds fit for monthly or for gynecological nursing. A board of examiners is already nominated, but the society has no right whatever to assume any such position.

The coroner's inquest on the bodies of the victims of the fire at Colney Hatch Asylum concluded yesterday. The jury found that "notwithstanding the fact of the

plans being sanctioned by the County Council, the Lunacy Commissioners and the Home Office, those authorities are greatly to blame." They say the building was unfit for its purpose, both in construction and materials, and could have been constructed of non-combustible materials in an equally short time. Some sensible recommendations are added and the highest commendation expressed of the heroic conduct of Dr. Seward, the nurses, and staff.

Prof. D. J. Cunningham, F.R.S., leaves Dublin for Edinburgh, having been invited to succeed to the Chair of Anatomy on Sir Wm. Turner being elected to the principalship.

OUR PARIS LETTER.

(From Our Special Correspondent.)

PASTEUR'S MONUMENT—DECREASE OF CRIMINALITY IN FRANCE—ROTHSCHILD'S CLINIC FOR CHILDREN—STATISTICS OF BARLOW'S DISEASE IN FRANCE—ROBIN'S REMARKS ON BOUCHARD'S COMMUNICATION TO THE CAIRO CONGRESS—EFFECT OF HEAT ON THE LECITHIN IN MILK—DEATH OF PANAS; OF VARNIER—THE USE OF IODIDES IN CANCER OF THE SKIN—POIRIER'S FIRST TWO LECTURES—LANNELONGUE AND LANDOUZY DECORATED BY THE GERMAN EMPEROR.

PARIS, February 18, 1903.

PASTEUR is, of course, to have a monument in Paris, but the place where it is to be erected has not yet been chosen. It was at first decided that it should be erected on the Place de Médecis, opposite the Pantheon, then opposite the Lorbonne, lastly in the avenue de Breteuil, opposite the dome of the Invalides. Just as work was to begin on the foundations, it was stopped, as the monument might impede the view of the Invalides.

It has been generally thought that criminality was increasing in France, and especially among the young men under twenty. The newspapers publish so many accounts of murders and thefts, that one is apt to get an erroneous impression. Reliable statistics furnished by the official journal of the French Republic show, on the contrary, that criminals have decreased in number steadily, and at all the periods of life.

A new polyclinic for the treatment of children's diseases was opened last month in one of the poor quarters of Paris. The establishment has been built by Dr. H. de Rothschild, one of the members of the millionaire family of that name. All the specialties, such as ophtalmology, laryngology, orthopœdic surgery, radiography, are represented. A large library, containing 10,000 volumes on children's diseases, is also a part of this dispensary. At a recent meeting of the Society of Obstetrics Dr. de Rothschild remarked that statistics showed that Barlow's disease was quite rare in France, only twenty-three cases having been seen so far. But it is frequently observed in Germany, where Baginski of Berlin sees eight or ten cases a year. Its maximum of frequency would seem to be in America, where already four hundred cases have been observed. This disease has been found by Baginski even when the child was fed at the breast. Professor Budin, said he had never seen a single case of Barlow's diseases, and as he employed sterilized milk, he considers that some other cause must be found. A report was made recently to one of the medical societies of Paris in which a certain variety of milk was spoken of as having been given to a child suffering from Barlow's disease. It is a noteworthy fact that in the reports that appeared even in the medical papers, no mention was made of this.

At the Cairo Congress of Medicine Dr. Bouchard made a communication on the modern tendencies of therapeutics, and declared that local treatment was apt to be even more beneficial than general treatment, and cited the advantages of treating, for instance, rheumatic arthritis by hypodermic injections of salicylic acid or one of its salts. Dr. Bouchard did not seem to wish to convey the idea that he was the inventor of this method, which has been used more or less in different ways. However, Prof. Albert Robin has written a letter to the *Presse Médicale* in which he remarks that he is astonished that Dr. Bouchard should not have mentioned the work he had carried out before him on this very subject. He then quotes a passage from his "Treatise of Diseases of the Stomach," in which he speaks of the use of drugs locally and of the small doses which can therefore be employed. Though Dr. Robin's recriminations hardly seem justified, the fact of his having seized this occasion to give them sufficient notoriety is not a cause for astonishment.

At a recent meeting of the Academy of Sciences, Bordas and Rackowski described the results of heat on the amount of lecithin contained in milk. It would seem that milk heated directly over a fire contains less lecithin than that which is heated in a bain-marie, or a vessel containing hot water, the amount lost in the first case being a third of the total amount, whereas in the second it is only a sixth.

The Paris Faculté de Médecine has lost two prominent men during the last month, Panas and Varnier. Professor Panas was a Greek, born in 1831 in Cephalonia, who came to Paris when he was a child, and was a naturalized Frenchman when he began his medical studies. He became an interne of the hospitals in 1854, the same year as Peter, Luton, Lécorché, Fournier, Marey. He was named surgeon of the hospitals in 1863, but did not begin teaching ophthalmology until 1873, as specialties were not highly considered in France until about that period. In 1873 he published his lessons on strabismus; in 1876 those on keratitis, in 1877 on affections of the lacrymal apparatus, and in 1878 those on retinitis and kindred diseases. On the 2d of February, 1879, Panas was installed as professor of clinical ophthalmology at the Hotel Dieu, a position which he kept until last year, when he was replaced by de la Personne of Lille. Dr. Panas was not only a skilful operator, but also a good lecturer, and his arguments were well chosen and clearly exposed.

Dr. Varnier was only forty-three years old when he died. He was known already outside of France as a man who had studied obstetrics in a thoroughly scientific manner. He was never satisfied with *à priori* doctrines or anatomical reasonings which were not founded on clearly recognized facts, and his works show his desire to be always accurate and painstaking. His latest work, "l'Obstetrique Journalière," is a finely illustrated work. Among his other works the best known, though unfortunately out of print, is "Introduction to the Clinical Study and Practice of Midwifery," which he wrote with Professor Parabeuf.

At a recent meeting of the Society of Dermatology, Dr. Salmon spoke of a treatment he had carried out for epithelioma of the nose, and which consisted in the use of tincture of iodine. There was steady amelioration. Dr. Darier, who is well known for his works on this subject, remarked that the patient who had been presented to the society was not cured, and said that he felt that practitioners could not sufficiently be warned against the use of drugs containing iodine, such as iodoform, and the like. The usual effect of such drugs is to whip up epithelial lesions. He had seen die, after four months, a patient who had a small epithelioma of the cheek, which was treated by a daily dose of 12 grams of iodide of potassium. Dr. Boudouier remarked that he had used erythrol, which is the iodide of bismuth and of cinchonidine. This drug disinfects the tissues, but does not hasten or retard the progress of the tumor.

Dr. Poirier, who has succeeded to Dr. Parabeuf as Professor of Anatomy, pronounced his first lecture on the 7th of January. The opening of his course was the cause of a good deal of excitement, as Dr. Poirier is a great favorite among many students. He is an excellent speaker, and generally manages to make witty remarks, when occasion requires it. Professor Debove, the dean of the faculty, is not so keenly appreciated, and as both men were present, the applause was mixed with signs of protest. At the second lecture the crowd was so great that it was found necessary to shut the doors of the lecture room, a measure which caused a certain amount of uproarious behavior on the part of the students.

Professor Lannelongue and Professor Landouzy, who are members of the Academy of Medicine, have been named knights of the royal order of the Crown of Prussia, as a consequence of the recent Congress on Tuberculosis held in Berlin.

OUR ALBANY LETTER.

(From Our Special Correspondent.)

ALBANY, February 26, 1902.

THE legislative mill is grinding, however little of grist, in the nature of new laws, is yet in evidence—accordingly the score or more of bills bearing directly and indirectly on medical matters are still in the throes. Wednesday the "Coroner's bill" had its inning before a legislative committee. Representatives of various medical interests advocated the abolition of the coroner's office and the substitution of the "medical examiner" as previously outlined in the MEDICAL RECORD, and as provided in the bill. The coroners and their friends vigorously opposed the change, and the matter now rests with the law-makers.

During the week Senator Amble has introduced a bill making more drastic the punishment for the sale of adulterated cream or milk, the sale of each separate can thereof being constituted a violation of the law.

On Wednesday the bill to provide for the examination, registration, and licensing of trained nurses by a State board appointed by the Regents was introduced by Assemblyman Brill. If this bill becomes a law (and we can learn of no opposition to this consummation), another year should be sufficient to solve the question of registering and con-

trolling midwives. It has been suggested that this can be done by exacting that on and after a given date every person, other than one previously registered as a midwife (the law, of course, not to apply to physicians), desiring to practise midwifery must be a registered nurse. Physicians will be interested in the fate of the bill introduced by the State Association of Public School Superintendents, in which the compulsory period in which children must attend school is changed from eight to sixteen to seven to sixteen years of age.

The Assembly Committee on Labor and Industries gave a hearing on the Child Labor Bill Wednesday of this week. It was claimed by those making a study of present laws that they are too lax, and that there was now unjust discrimination against messengers, laundry and bakery boys, and others of the younger among the employed.

In a Senate bill introduced during the week, provision is made for the incorporation of the "Society for the Investigation and Improvement of Sanitary Methods," capital stock, $50,000. The corporation is empowered to conduct experiments and encourage investigations in sanitary science, and promote the practical application of methods of scientific knowledge. The incorporators are Edward D. Tompkins, Louis Chable, Lawrence Barnum, and Albert G. Weed.

Medical men are actively engaged in the "fight to a finish" between the Regents' office and the State Department of Public Instruction. It is said that the Regents' bill calling for the unification of educational interests under their supervision will be introduced shortly. A clear-cut issue is thus made, and judging from the tenor of editorial articles in the lay press, and in the leading educational journals, the best elements of the community will favor the bill. The State Homœopathic Medical Society, at its annual meeting, resolved in favor of Regents' control and the Legislative Committee of the Medical Society of the State of New York has issued a letter to the Deans of the various State medical schools asking their coöperation in the same direction. It is creditable to the State that its citizens in all walks are so earnestly engaged in the discussion of this issue, and it is equally creditable to the profession that until now no voice of prominence from among those in its ranks has been heard other than in advocacy of the divorce of politics from school issues as contemplated in the bill for unification of all educational interests under the control and supervision of the Regents.

A prominent State senator in conversation with the writer wanted to know why it was that health officers and other executives, whose deputies and assistants must needs be physicians, do not object to civil-service laws applying to such appointees. He said: "Under present laws the State vouches for a doctor by placing its seal as to his medical ability on his license. The State has appointed boards of medical examiners for that purpose. Now these men are competent or they are incompetent, and unless the degree of Doctor of Public Health is established, it becomes farcical to ask doctors of medicine again and again to submit to examination if they want to hold public medical office. There are as many grades of lawyers as there are doctors, but what would be said if the District Attorney of New York or of Kings County were to have to await the pleasure of the Civil Service Board before appointing deputies? Still, this is just what the Health Officer has to do." There is but one answer to this argument: "Create the title of Doctor of Public Health, and make every one such eligible to any office of medical trust in the State."

Assemblyman Dickinson's bill, designed to permit females injured (in cases involving suit for damage) to have at least one physician of their own sex present at a physical examination compelled by the defendant, was discussed for a whole hour in the Assembly chamber on Wednesday, and notwithstanding pronounced opposition (the vote was 62 to 61) on medicolegal points, the bill was advanced.

Senator McCabe of Brooklyn has introduced a bill permitting the State Commission in Lunacy to appoint a medical inspector, salary, $5,000 yearly, whose duty it shall be to examine the patients in State hospitals. He shall be "a well-educated physician" and have actual experience in an institution for the care of the insane.

Syphilitic Phlebitis.—Gaucher and Chiray have observed a case of syphilitic phlebitis of the superficial veins of the arm. This phlebitis came on in the course of an attack of syphilis, which began by a chancre, and during the secondary stage. The writers insist on the absence of every other cause but syphilis to explain the venous thrombosis. They conclude that the existence of a syphilitic phlebitis with this evolution is due exclusively to the specific toxic infection of the blood.—*La Bulletin Médical*, January 31, 1903.

"ELECTROTHERAPEUTICS AND QUACKERY."

To the Editor of the Medical Record:

Sir: With the spirit of your editorial note on this subject in the issue of February 28, I am in full accord. If, however, by quacks are meant men who are in no way reputably affiliated with the medical profession—then the statement of Mr. Edmund Owen before the British Electrotherapeutic Society—"that the medical use of electricity has fallen largely into the hands of quacks," is quite erroneous. This could truthfully have been said twenty-five years ago, but not now. Quacks of this kind are quite as effectually driven from the field as are the advertising oculists and aurists and throat specialists. Electricity, as has been well said, "has been wounded in the home of its friends." In the same way as the *x*-rays, valuable as they are, have been made to stand for more than they have yet accomplished, so the various electric modalities, and especially static electricity have been lauded too much as cure-alls to satisfy rational medical conservatism.

You very properly dwell upon the significance of the fact that there are "hordes of users of this method whose voicings betray their ignorance of even the elements of electrophysics." It is this class, undoubtedly, that is in the main, but not altogether, responsible for the unfavorable judgment of the profession at large. I can hardly agree, however, with the editorial statement that there are "scarcely a handful of reputable authorities in the world to-day who have any faith in, or knowledge of, the therapeutics of the static form of electrical manifestation." There are hunndreds of reputable and able men both here and abroad who fully recognize the influence of the various methods of electrization over general and local nutrition. As to those who have "no knowledge of electrical manifestations, and so have no faith," it can only be said, so much the worse for them. If they possessed more knowledge they would have more faith.

How often is heard the remark from a medical standpoint, "I do not believe in electricity." Could anything be more senseless? One might as well say, I do not believe in heat or cold, or in any of the marvelous manifestations of universal force, upon which life and physical well-being depend. It is gratifying to know that the reproach of Mr. Lecky "that the medical powers of electricity which of all known agencies bears most resemblance to life, are unexplored," is no longer deserved; and if, in these explorations, there is developed with what is substantial and worthy, too much that is chaff and worthless, it is only another illustration of that dominant commercialism which, while it may abstract, cannot prevent scientific advancement or professional recognition.

A. D. Rockwell, M.D.

February 28, 1903.

HOW TO INCREASE THE IMPORTANCE AND MEMBERSHIP OF STATE MEDICAL SOCIETIES.

To the Editor of the Medical Record:

Sir: Perhaps most of your readers will agree with me when I say that the medical societies of our States have nothing like the membership they should have, and, in consequence, they fail to command the respect of the people and legislators that they otherwise would. When a State society through its committee asks for certain legislation of a medical character, it does not effect so much when it becomes known that the society has only one-tenth of the medical men of the State in its membership. To accomplish much for the public or its members, it should have nearly the whole profession of the State on its rolls. It is probably true that nearly every physician should wish to become a member of his State society; but then, as a matter of fact, not one-seventh care to do so under the existing arrangements.

It may not be possible for any one to tell just why so many of our profession do not care to belong to or attend the State societies; but some reasons may be given. Many are too busy and do not care to leave their patients that long, or to the care of another. Others believe they can get everything of value that transpires there in the medical journals. There are yet others who assert that a certain few are always kept in office and use these societies to minister to their vanity, etc. Even these malcontents will often admit the necessity of presenting a more united front upon the questions that concern both the public and our profession.

Through the reports of the State boards, every man who would be acceptable as a member of the society is easily known. After urging these to join in the regular

way, three-fourths would still be found on the outside. Yet the influence and votes of these men are often needed in the interests of the profession.

If these societies would arrange three classes of members they might have nearly all of them in their organizations. In the first class I would have the present membership. In the second, all those who would wish now and then to attend its meetings only, and who might be allowed to belong for, say, fifty cents a year. When they did choose to attend, then for that year, they would pay the regular annual dues. In the third class could be placed all the rest who were not to be gained for the society under the first two plans. It should consist only of reputable men, and membership should be given them free, or, possibly, they should be required to pay fifty cents or one dollar to the society for its certificate of membership. Then when questions of importance came up, upon which it would be desirable to have the voice of the whole profession, the sense of the members could be detained by a postal-card vote, and the society could then come before the people, or their representatives assembled, and find that its voice would be more powerful.

An objection to be urged will no doubt be: Would such a course be just to those who have borne the burdens up to this time? Perhaps not, yet we need the help of these reputable men, and we have never yet been able to get it under the old plan. These men are self-reliant, for they seem willing to get along without the society, and I do not see why we should fail to recognize facts as they exist, and proceed to mold them to our aid, and not blindly kick against the pricks.

Many of these men have great influence in the communities in which they practice. They may have little money, but their friends and patients revere them, and the society can obtain much of that influence, and give them in return the certificate that will show that they are recognized outside of their own county. This is not, therefore, a wholly one-sided deal, as might be thought upon first cosideration.

The Illinois State Medical Society, at its last meeting, took a step in this direction when it decreed that all members of the county societies throughout the State should become members of the State organization. I believe they have not definitely defined the status of these new members as to the annual dues they must pay, but I have been informed that it is to be very liberal. Even with this great increase, our society has only increased its membership to 4,200. The report of our Board of Health for 1902 gives us over 16,000 licensed practitioners, of whom it is safe to say that 12,000 could belong to our regular State society. As a result of this action of our State society, a great step in advance, the membership has been brought to an approximate third of the profession in the State, who might and should belong to the State society.

As all recognize the truth, that in union there is strength and prosperity, while in disunion and factional fighting there is nothing but weakness, it would seem to be the part of wisdom to set our faces resolutely toward a better state of things, and try to bring it about as soon as possible.

S. J. Bumstead, M.D.

Decatup, Ill., February 13, 1903.

Diseases of the Cornea in Children.—C. Devereux Marshall wishes more especially to draw attention to cases which are considered and are in reality less serious than interstitial keratitis, namely, phlyctenular ophthalmia. It is, however, by no means always a simple disease, but may lead to ulceration, opacity, and even perforation of the cornea. For the successful treatment of the condition, one must study and be acquainted with the morbid processes which accompany it. That it is of an eczematous nature few will deny, and it is also a fact that it occurs far more frequently in underfed and badly nourished children than in any other class of the community. Its most distressing symptom is photophobia, and its most serious result is impairment of the transparency of the cornea, caused by the nebulæ which remain. The author protests against the the use of iron, which in the earlier stages aggravates the irritability of the eyes. He uses: Grey powder, 2 grains; powdered belladonna leaves, 1 grain; and sugar of milk, 2 grains; half a powder twice a day. In addition atropine drops of a solution containing three grains to the ounce should be employed, and the eye should often be bathed with boracic lotion. For the cure of the photophobia, setons, the blowing of calomel, blisters, etc., should never be used. One of the chief causes of the condition is the development of fissures and excoriations at the outer canthi. The best treatment is to give an anæsthetic and to stretch the lids as widely open as possible. This will cause bleeding, but after it has ceased the lesions will heal.—*The Practitioner*, January, 1903.

Progress of Medical Science.

The Boston Medical and Surgical Journal, Feb. 26, 1903.

The Use of Cargile Membrane in the Nose in Order to Prevent Adhesions.—Harris Peyton Mosher has found that by folding the membrane into a wedge-shaped strip, several layers thick, it would introduce more easily, and could be packed firmly between the two cut ends of the adhesion. It will then stay in place several days before it needs to be replaced. He has used it in turbinates after cauterizing, in order to keep the cauterized turbinate from cauterizing the septum opposite, and he has used it on the raw surface left by sawing off a spur. Other uses in the nose which readily suggest themselves are: as a dressing on the septum after the operation for the correction of deflection; as a sleeve for a packing which has to be left in the nose for any length of time; to hold down flaps of mucous membrane after the submucous dissection of cartilaginous spurs; as a guide and stimulant to the growth of epithelium, in order to prevent the formation of a perforation, and in order to help toward the closure of perforations after the refreshing of their edges, and as dressing for the cartilage of the septum whenever it is found to be exposed.

The Treatment of Hemorrhoids.—John O'Connor describes the Whitehead operation, which he considers far the best in these cases, as it avoids complications due to injudicious encroachments on the skin when separating it from the mucous membrane. Artery forceps is applied to the four cardinal points of the rosette or, if the case be non-protrusive, the forceps is applied at same points about one-third of an inch from skin margin. The mucous membrane is separated from underlying structures by passing, the left index finger into rectum, while with a blunt dissector, and an occasional snip of the scissors, the mucous cuff is raised, and separation carried well above pilous zone. By the four artery forceps originally applied, the cuff of mucous membrane is drawn outward, and it is transversely divided above pile area. In doing this it is necessary to determine the extent of each scissors' snip by the amount of hemorrhage, every spurting vessel must be at once caught up by the forceps, and by working around in this manner it is surprising how little blood is lost. All hemorrhage having been effectually arrested, the part is well irrigated with warm salt lotion, and the mucous membrane is attached to the skin by a continuous catgut suture. This suture must not be drawn too tight, or necrosis of tissues will follow. And under no consideration should this suture be utilized as a suture ligature to choke hemorrhage, for it invariably fails, and collections of blood occur beneath the mucous membrane.

A Few Remarks on Blood-pressure.—James Marsh Jackson describes his experiences with the Gaertner blood-pressure machine. In a series of cases of exophthalmic goiter which he has followed for over two years, and in which he has used bromide of quinine, he has found no variation in the blood-pressure of any account. These cases have nearly all had a pressure ranging from 120 to 160; that is, they were above the normal. As an aid to diagnosis, the blood-pressure is fast taking an important place. We know, for instance, in arteriosclerosis the blood-pressure is high; in chronic nephritis, especially of the interstitial type, the pressure runs very high, and in a way the amount of tension is a good index to the extent of the disease. The best use to which the author has put the instrument has been in the demonstration of tension to students. The blood-pressure in a young healthy man ranges from 100 to 130 mm. of mercury; in young women the pressure is decidedly lower, and ranges from 90 to 110. Elderly people almost always have an elevated pressure, due for the most part to changes in the arteries. Low pressures are uncommon, except in cases of shock and collapse. Pressures of 200 are not infrequently found, and should always be considered more or less dangerous, while pressures of 250 are very dangerous, and are only seen in grave cases. In the last year five of the author's patients with pressure of over 190 have died of apoplexy, and he now makes it a rule to warn the family of a patient with a tension above 190.

Journal of the American Medical Association, Feb. 28, 1903.

Perforation of the Normal Intestine by an Ascaris Lumbricoides.—The patient of L. C. Ager was an American man, aged thirty-six years. When first seen he was suffering from diffuse abdominal pain. A later localization of symptoms led to a diagnosis of appendicitis, and the abdomen was opened. There were indications of intestinal perforation, but the condition of the patient was so bad that no search could be made. Death resulted in twelve hours. Autopsy was held six hours later. On opening the abdomen a large amount of mucopurulent fluid gushed out. There was an acute exudative

peritonitis most marked in the right lower quadrant. The intestines were matted together with an exudate, in some places a quarter of an inch thick. On separating the coils of intestines a living lumbricoid was found. After a short search a small round perforation was found in the small intestine, about ten inches above the caput coli. On opening the intestine no other lumbricoid was discovered, and the mucous membrane seemed, except for the clean-cut perforation, entirely normal. The literature of this class of cases is briefly reviewed and a bibliography appended.

Some Notes on Aural Vertigo.—B. A. Randall says that in the great majority of cases that have come under his observation neurotic and general vasomotor influences have seemed to lie at the bottom of the trouble, except in the considerable number of cases in which catarrhal affections of the Eustachian tubes and tympanum was so clearly at fault that catheterization could be fairly expected to afford relief. He says that in all cases of vertigo coming to the otologist he should employ minute methods of study as to the tympanic and labyrinthin condition, but also investigate personally or through the aid of a judicious physician all the general aspects of his patient's case. He should exclude or relieve all involvements of the accessory nasal cavities, investigate the refraction and muscular relations of the eyes, as well as learn whatever teaching may be given him by the eye-grounds and, abating nothing of the local treatment by inflation and massage, which the aural condition may seem to demand, and using strychnia and other tonics according to the general needs of the patient, he may yet employ as a direct and almost specific means of treatment this vigorous vascular tonic, which has been given us in the adrenal extract.

The Fly as a Carrier of Typhoid Fever.—Alice Hamilton contributes a careful, illustrated study of the part played by the fly in the recent Chicago typhoid epidemic. Her conclusions are as follows: (1) The epidemic of typhoid fever in Chicago during July, August, September, and October of 1902 was most severe in the ward, which, with one- thirty-sixth of the city's population, had over one-seventh of all the deaths from this disease. (2) The concentration of the epidemic in this locality can not be explained by contamination of the drinking water, or of food, or on the ground of ignorance and poverty of the inhabitants, for the ward does not differ in these respects from several other parts of the city. (3) An investigation of the sanitary conditions of this region shows that many of the street sewers are too small, and that only 48 per cent. of the houses have sanitary plumbing. Of the remaining 52 per cent. 7 per cent. have defective plumbing, 22 per cent. water closets with intermittent water supply, 11 per cent. have privies connected with the sewer but without water supply, and 12 per cent. have privies with no sewer connection. (4) The streets in which the sanitary arrangements are worst had the largest number of cases of typhoid fever during this epidemic, irrespective of the poverty of the inhabitants. (5) Flies caught in two undrained privies, on the fences of two yards, on the walls of two houses, and in the room of a typhoid-fever patient were used to inoculate eighteen tubes, and from five of these tubes the typhoid bacillus was isolated. (6) When the discharges from patients with typhoid fever are left exposed in privies or yards, flies may be an important agent in the dissemination of the typhoid infection.

The Clinical Application of Some Thyroid Experiments.—L. Breisacher instituted a series of experiments in which chemical and electrical irritation was applied to the various cervical nerves without, however, producing in any case symptoms resembling those noticed in thyroidless animals. To definitely decide this question the writer devised the following method of experimentation: First, the left vagosympathetic and the superior laryngeal nerves were extirpated, the superior incision being made at the superior ganglion and the lower incision half an inch below the lower border of the thyroid gland. The animals were carefully observed during a period of three weeks following the operation; they remained perfectly normal. Following this period the right thyroid gland was totally extirpated and the animals again carefully watched for a period of three weeks, during which time they remained in an absolutely normal condition. Finally the thyroid lobe on the side on which the vagosympathetic had previously been removed was extirpated, and it was shown that the dogs succumbed in precisely the same manner as did the dogs in whom this method had not been resorted to, thus proving that nerve irritation is not absolutely necessary to the production of death after total extirpation of the thyroid gland. The negative results obtained led the author to further experiments on the influence of the feeding of milk, eggs, and raw and boiled meat on animals deprived of their thyroids. These experiments consisted in keeping dogs on a diet of milk or milk and eggs for a number of days and then performing a total extirpation of the thyroid gland, or a partial extirpation, and then finally a total extirpation, and thereon noting the influence of a milk, egg, boiled and raw meat, and beef-broth diet. It was shown that 30 per cent. of all animals fed on a milk or boiled meat diet, particularly a milk diet, remained entirely healthy, but died when put on a raw-meat or beef-broth diet. All of my animals that were fed on raw meat from the beginning of the experiment succumbed to the operation. These experiments then furnished the first evidence of the metabolic significance of the thyroid gland to the organism, and, further, that a milk diet acts more favorably than a raw-meat diet in dogs in whom a total thyroid gland extirpation has been performed. The general therapeutic conclusion is that in myxœdema, it is advisable to withdraw meat from the dietary, substituting therefor milk and eggs. The same rule is applicable to the treatment of cachexia strumipriva and Basedow's disease.

New York Medical Journal, February 28, 1903.

The Diagnosis and Treatment of Contracted Pelvis.—W. R. Gilman does not believe it is safe to rely solely on the pelvimeter in estimating the internal pelvic diameters. We must measure per vaginam, and in order to reach the promontory of the sacrum it is necessary to direct the fingers well upward toward the abdominal cavity, not backward toward the concavity of the sacrum, and to have the elbow and forearm well below the level of the vulva. The ulnar side of the examining hand is forced against the perineum; and it is evident that the examination is more easily made if the patient is a multipara with a patulous vaginal orifice and a relaxed perineum. If the patient is a primipara with a firm perineum, it may be necessary to give an anæsthetic. The obstetrical conjugate, being the shortest diameter of the pelvis, may properly be regarded as a guide or measure of the size of the pelvis; and for practical purposes it is the only measurement which it is absolutely necessary to make, except in unusual cases of very marked deformity. If it reaches the normal standard of 11 c.m. (4½ in.), it is safe to infer that the pelvis is of average size. If the obstetrical conjugate is 9 c.m. forceps or version will usually result successfully, the latter being preferable to the high forceps' operation. When the conjugate is 7.5 c.m. (3 inches), forceps or version may occasionally be successful; but extraction through such a pelvis is usually very difficult and likely to prove fatal to the child. It is in pelves of this size that symphyseotomy is indicated. This operation is one that prepares the way for forceps or version. It increases the conjugate by 2 c.m. (¾ inch), and makes delivery by forceps or version safe. The operation should be restricted to those cases in which one is certain that only a very little more room is needed for a safe delivery by forceps or version. Although children have been delivered safely by symphyseotomy through a conjugate of 7 c.m. (2¾ inches), it is safe to place 7.5 c.m. (3 inches) as a limit. When the conjugate is 7 c.m. (2¾ inches), or less, the choice of operation lies between induced labor and Cæsarean section.

Hypodermoclysis: Experiments, Technique, and Clinical Uses.—R. C. Kemp advises the observance of the following precautions: (1) Allow the fluid to flow slowly, so that the tissues may not be over-distended and that absorption may readily occur. (2) To avoid entrance of air into the tissues, the fluid should flow from the needle at the moment of puncture; also the vessel containing the fluid should never be allowed to become completely emptied. (3) Do not inject directly into œdematous tissue—dropsy of the organs, or serous cavities, is not a contraindication to hypodermoclysis, which is of value to aid elimination by its diuretic action. (4) Regarding the needle employed it should be pushed in semi-obliquely and steadily, and not plunged in suddenly. Beware of injuring vessels and nerves. It is not advisable to inject into muscular tissue, as painful lumps, or even abscesses, may result. (5) If the flow from the needle ceases, push it in slightly and then withdraw it a little, or else rotate it. This will generally free it from the obstruction. The preferable site for injection is the iliolumbar region between the iliac crest and twelfth rib. The solution should consist of 0.6 per cent. of salt water, boiled and filtered. The amount of the injection is based on the rule of one drachm to every pound of body weight. This will be taken care of by the kidneys every fifteen minutes. The injections may be repeated several times daily. The following are the indications for its use: (1) Hypodermoclysis increases the quantity of fluid in the vessels, by replacing that which has been lost, as from hemorrhage or diarrhœa; it

adds fluid to the circulation, and thereby acts as a stimulant to a rapid and feeble heart, as in shock. (2) It dilutes the poison of disease and aids in the elimination of toxic products through the diuretic action on the kidneys, as in sepsis, or in uræmia. (3) It causes profuse diuresis and relieves renal congestion, as in uræmia, oliguria, or in acute congestion of the kidneys. (4) The saline injection is asserted by many to have a hemostatic effect, and is thus given in hemorrhage, as from gastric ulcer, intestinal ulcer, or in pulmonary hemorrhage.

American Medicine, February 28, 1903.

Cancer Statistics in the Twelfth Census of the United States.—Harris Moak concludes that: Cancer and tumor have not increased in any greater proportion than several other diseases "common in adult life and old age." The geographic distribution of cancer and tumor corresponds almost exactly to the geographic distribution of people of greatest age. Cancer and tumor are, therefore, most frequent in those sections where old people are most numerous.

Are Antiseptics of Any Value in Hand Disinfection?—Edgar R. McGuire presents the following conclusions: Absolute sterility of the hands is impossible by any method. There is no royal road to sterilizing the skin—nothing takes the place of long and vigorous mechanical scrubbing. The longer the hands are scrubbed under aseptic precautions the nearer the approach to sterility. The use of antiseptics on the skin is, at least, questionable; under the usual conditions, it is distinctly harmful. When the true value of antiseptics is understood we shall have cleaner hands, due to more conscientious scrubbing. The use of rubber gloves, while not ideal, is the nearest approach to it. The operator whose hands perspire freely ought to wear gloves in every case, regardless of all objections to them.

Chronic Diarrhœa.—Edwin Zugsmith affirms that the onset of chronic diarrhœa is usually insidious, although the initial symptoms may be more or less acute. The prognosis is not so bad as is often supposed. Treatment requires careful attention to detail, and persistence. The indications are: to correct the digestive fault which has been the primary cause of the trouble, and to repair the damage that has already been done. Diet and hygiene are of prime importance. The diet must be strict and careful with reference to idiosyncrasy. Food must be carefully prepared. In severe cases it may be necessary to restrict the diet to milk alone, or to egg water. Under hygienic measures should be included the external use of water, rest, exercise, massage, travel, and residence at health resorts. Mineral waters are of advantage, those containing calcium salts being the most generally useful. The bitter tonics serve a good purpose. Non-absorbable oils, as castor-oil, are effective in soothing the inflamed bowel.

Philadelphia Medical Journal, February 28, 1903.

Is Nephroptosis Hereditary?—John G. Sheldon mentions five cases of this affection which occurred in one family, and reports two cases occurring in children. One of the latter was a boy of eight years who was subject to "spells of sickness in his stomach, pain in the right side, nausea, and headache." He rarely vomited. Excitement or violent exercise seemed to precipitate them. His right kidney was found to be displaced downward and was freely movable. Nephropexy was advised and performed and entirely relieved the symptoms.

A Case of Trigeminal Neuralgia Complicating Typhoid Fever.—Charles J. Aldrich has under observation a patient who suffers from severe and persistent trigeminal neuralgia, which developed in the convalescent period of a typical attack of typhoid fever, and which has continued for three years. This pain became so severe as to cause the jaw to "lock," so that the mouth could not be opened. The left side of the face was swollen, and a point of marked tenderness was noted just in front of the left ear. Nearly all of her teeth, though sound, were drawn. All the reflexes are normal, and except for the slight ocular paralysis, deafness of the left ear, and the neuralgia, she is a healthy young woman. Whether this neuralgia is due to changes, which took place in the nerve itself, due to nutritional disturbances or to toxic agents, or whether it is a pressure neuralgia from some swelling and tumefaction of the periosteum or other tissues along its course, it is impossible to ascertain.

Sixth Lecture in a Course on Tropical Diseases, Etc.—Charles F. Kieffer continues the consideration of abscess of the liver. Rigidity of the muscles is not present, as a rule, in these cases, although rigidity of the right rectus, particularly of the upper part, has been observed in traumatic abscess when located low down in the thin edge of the liver. The most important step is the prompt and energetic treatment of the amœbic dysentery. The use of protargol in dysentery has been used with excellent success, in injections of a 1-per-cent. solution. If there are acute dysenteric symptoms, they should be eliminated by the use of ipecac or the salines. Next, the chronic congestion of the liver should be relieved. A free exhibition of the saline sulphates is sometimes of the greatest service in the depletion of the portal system. When malaria is present, quinine may have a favorable effect on the inflamed liver. When pus has formed in the liver, the indication is for prompt and thorough evacuation. In all needle punctures of the liver, the main danger lies in wounding the inferior vena cava. Hepatic phlebotomy is a very valuable means of reducing congestion of the liver. Exploration of the liver for suspected pus must be thorough and searching. The method with trocar and cannula is particularly applicable to deep-seated suppuration in the liver, particularly when the pus is found posteriorly or in the dome. The operation by incision may be either through the abdominal wall or through the thoracic wall. Ordinarily the abscess is not washed out. If the sac be very large, making a counter opening necessary, then washing of the sac is safe. If the symptoms are not much improved after operation, another focus has probably formed and must be searched for.

The Lancet, February 21, 1903.

A Case of Hæmophilia Illustrating the Value of Calcium Chloride as a Local Styptic.—T. W. Parry's patient was a boy of seven and a half years, who, when first seen, was bleeding from a cleft between the left lower first permanent molar and the temporary molar immediately in front of it. No other source of blood could be discovered, even under anæsthesia. All sorts of styptics were used on cotton pledgets packed between the teeth, but without avail. Finally the hemorrhage was checked by plugging the cleft with cotton dipped in a solution of calcium chloride 30 grains to the ounce.

A Note on the Use of Carbolic Acid in the Treatment of Smallpox.—J. T. Neech has had success in several cases of smallpox from the application of pure carbolic acid to the rash. Applied in the vesicular stage, the vesicles either dried up into crusts or their contents were absorbed and the epidermis inclosing the vesicle fell off. The acid was carefully applied on a camel's hair-brush to the rash over a certain area of the body each day, the face and head being the area selected for the first day. The treatment seemed to cut short the disease, the secondary suppurative fever was averted, there was no pitting, and the offensiveness of the pustular stage was avoided. In addition, the infectiousness of the patient was materially diminished. The statements made are based on an experience of only four cases, one severe, one moderate, and two light.

Some Thoughts and Observations Regarding Appendicitis, Especially When Appearing in Its Acutest Forms.—J. A. MacDougall discusses the early literature of typhlitis and perityphlitis, and traces the gradual discontinuance of these terms and the substitution therefor of the present appellation of appendicitis. He is disposed to believe that right iliac inflammations have increased during recent years, both in frequency and severity. He also notes an increase in the number of relapses and the fact that certain families seem predisposed to the malady. He is not of the opinion that the diagnosis of the disease carries with it inevitable surgical intervention, but states that in the very large majority of cases the prognosis, when the case is under careful medical supervision, is a favorable one, though admitting that there are certain exceptional examples in which the recovery of the patient rests largely with the surgeon. Early operation does not increase a peritonitis already in existence but rather cures it. Conditions simulating appendicitis are appendical colic, renal and hepatic colic, certain intestinal obstructions, suppurating Fallopian tubes, pelvic peritonitis in women with associated gonorrhœa, twisting of the pedicle of ovarian cysts, and perforations of the stomach and bowel. Occasionally typhoid fever is ushered in with acute right iliac symptoms. The paper is in the main a plea for early diagnosis, and in grave acute cases for prompt operative measures.

Aneurysm of the Ascending Arch of the Aorta in a Small Boy; a Post-mortem Surprise.—The patient of A. C. Jordan was six and one-half years old, and had suffered for two days from headache, vomiting, and double otorrhœa with some fever, but no tenderness over the mastoid. Later the temperature rose, but the other symptoms subsided. A few days later the left knee commenced to swell and effusion appeared in the joint. The general condition improved from this time, but in a few days later, while the boy was sitting up in bed playing

with his toys, he suddenly turned pale and died. There had been no kidney or eye symptoms. Autopsy showed the heart incased in a blood clot, and on the anterior face of the ascending aortic arch was a sacculated swelling, in the center of which was a horizontal slit-like opening. On the corresponding point of the inner surface of the aorta was a triangular opening with sharp edges. The flap, along with the shortest side of the triangle was pushed outward into the lumen of the sac. Evidently a small opening in the intima had occurred and the blood had leaked through it, causing a limited bulging of the fibrous coat of the aorta. The intima had thus lost the support of the fibrous coat, and some slight exertion had led to a sudden enlargement of the opening. There were no other abnormal conditions about the heart. The patient had been repeatedly examined, but no abnormal cardiac signs or symptoms had been made out. There had been no history of a chest wound or injury of any sort. It was thought that there might have been a septic aortitis from infection derived from the ears. There was evidently sepsis in the system, as shown by the knee symptoms.

British Medical Journal, February 21, 1903.

Antityphoid Serum as a Curative Agent.—B. Baskett gives his results from the use of antityphoid serum which are most encouraging. He has now used it in four cases. The dose he gives is uniformly 10 c.c. He reports here the case of a man of twenty-eight years who was seized with the fever on July 14. On July 26 the writer injected the first dose of serum. The temperature, which was in the neighborhood of 104° fell to 99.8°. By August 20 the man was well.

Case of Gonorrhœal Gingivitis.—Sidney Vines had under his care a middle-aged workingman suffering from gonorrhœa. About a month after the disease was contracted, the gums became sore. They were red, swollen, and spongy, and there was an over-abundant flow of saliva. In a few days he presented an appalling spectacle. Every tooth was loose and bathed in pus, which oozed from every socket. He could not eat, and drank with difficulty. His temperature was 101° F. Gonococci were present in a swab taken from the gums. Nitrate of silver solution was applied to the gums twice daily, and a mouth wash of potassium permanganate ordered. In a few days the symptoms began to abate. Tonics were given and the patient ordered to paint his gums many times a day with equal parts of glycerin and the strong solution of perchloride of iron. He had carried the infection to his mouth by means of a wooden toothpick.

A Note on Some Uses for Picric Acid.—F. Victor Milward states that the lesions in which picric acid is particularly helpful are those in which the loss of superficial epithelium has produced a raw and painful sore, discharging serum and seropus. Picric acid is a coagulant and an analgesic. It is a simple and effective remedy, and promotes rapid healing. It is best used in a saturated solution, 1 in 95 of distilled water. Should active inflammation be present, there is danger of confining microorganisms under the protective coatings, and of giving rise to further inflammatory trouble. It is not suitable, for instance, in acute eczema. Peri-onychia is very amenable to this treatment. The soft parts are thoroughly separated from the nail by the head of a large needle and a few threads from white gauze soaked in the saturated solution pushed to the bottom of the cavity. This is renewed three times daily. The remedy is also of use in the treatment of soft corns, and ingrowing toe-nail, and in some cases of intertrigo. Picric acid seems to cause no irritation to the tissues. Its use should be very thorough.

The Lettsomian Lectures on the Conditions Which Modify the Characters of Inflammations of the Skin, and Their Influence on Treatment.—H. Radcliffe Crocker declares that inflammations of the skin comprise more than half of all skin cases. The inflammations set up by irritants differ according to the strength of the irritant. Vulnerability to certain irritants once acquired often increases till the very slightest exposure is sufficient to bring on an attack. In discussing the pathology of eczema, the papulo-vesicular type is taken, and of it the pathology is still a matter of dispute. The various inflammations due to the staphylococcus aureus are given, as well as those due to the streptococcus of Fehleisen. The modifications of dermatitis produced on a seborrhœic basis are discussed, and it is shown that seborrhœa oleosa is now again regarded as excess of secretion from the sebaceous glands, and not from the sweat glands. The local origin of general eruptions is considered. The most feasible explanation is that there is first an invasion of a microparasite from without, and this undergoes local multiplication, or perhaps a toxin is formed, and then internal absorption into the circulation and generalization from within outward.

Deutsche medicinische Wochenschrift, February 5, 1903.

Cutaneous Mercurial Reaction in Syphilitics.—Rille refers to the recent article of Herxheimer and Kraus upon this subject. The latter, in their perusal of the literature, have found the reaction previously mentioned only by Jarisch and Jadassohn. Rille in his recent work (1902), makes especial mention of the reaction, and describes its characteristic features. The reaction and its significance is also mentioned by K. Baer (Rille's assistant) in his article in the *Wiener medicinische Wochenschrift*, 1902, No. 31.

Etiology of Dysentery.—L. Rosenthal, during the epidemic last year in Moscow, studied eighty-five cases of dysentery. From all of these Shiga's bacillus was isolated. This microorganism was found regularly in the stools, but never in the blood or urine. Thirty cases were submitted to agglutination tests with this bacillus, and in every instance a positive result obtained. Usually the reaction first appeared from the tenth to the twelfth day of the disease. It was then usually present in a 1 to 40 or 50 dilution. Control tests with other bacilli, such as typhoid or colon were always negative. Fourteen cases were examined post mortem. In all Shiga's bacillus was found in the superficial and deep layers of the diphtheritic-like membrane which covered the intestinal mucosa. Only in three cases were the bacilli found in the mesenteric glands. In one case the organisms were found in the liver and spleen. So far as tried, the bacillus has been found non-pathogenic for cats, dogs, rabbits, and guinea-pigs, but the tests thus far tried are too limited in number to permit of definite conclusions. The bacilli remain alive in dysenteric stools kept at the room temperature, or even at 0°C. from eight to eleven days. Upon fruits or vegetables they remain alive from seven to eight days

Berliner klinische Wochenschrift, February 9, 1903.

Accommodation Paralyses.—Josef Helbron considers the etiology. Usually there is only a paralysis of the ciliary muscle, but occasionally disturbances of the pupils are present. One hundred and three cases have been observed by the author during the past two and one-half years. The etiology may be considered under three subdivisions: (1) Diseases of the nervous system. These include diseases of the central nervous system, tabes, and the various neuroses. (2) Infectious diseases: Syphilis, tuberculosis, diphtheria, influenza, and rheumatism. (3) Intoxications: Alcohol, tobacco, belladonna, stramonium, hyoscyamus, etc. In addition to the above, accommodation paralyses have occasionally been observed following severe and prolonged gastrointestinal affections.

Rigidity of the Back Muscles.—H. Senator reports a case which came under the observation of Dorendorf two or two and one-half years ago. This condition has been described by some under the name of deforming spondylitis or spondylosis rhizomelica. During the last two years there has not been much change in the patient's condition, although at times, under anti-rheumatic treatment, and massage, temporary improvement has taken place. It is probable that the bones of the spinal column are not involved in the process, although secondary lesions in these bones undoubtedly occurs in some cases. The bony lesions are, however, never primary. The etiology of the affection is not clear. This patient had had both syphilis and gonorrhœa. The myositis following these diseases is, however, never diffuse, such as is seen here. Here the trouble began with an attack of lumbago, and the effect of treatment would seem to indicate the rheumatic nature of the trouble.

Münchener medicinische Wochenschrift, Feb. 10, 1903

Ileus Resulting from Thrombosis of the Mesenteric Vein.—A. Reitzenstein reports a rare case which was diagnosed during life and confirmed at autopsy. The clinical picture was characterized by a gradual appearance of the symptoms, sudden intermissions in the pains, little general or local meteorism, the hemorrhagic ileus and the marked hemorrhagic diarrhœal passages. The autopsy showed a large thrombus in the mesenteric vein. The etiology of the lesion could not be determined.

Surgical Intervention in Stricture of the Œsophagus.—H. Linder says that surgical intervention in stricture of the œsophagus due to malignant growths yields at the best unsatisfactory results. Only those cases are suitable for radical operation (removal of the tumor) in which the new growth is limited to the upper portion of the œsophagus. Even here the results are discouraging. Linder has operated upon three, all of which terminated fatally shortly after the operation. In most cases the establishment of an artificial gastric fistula through which nutrition can be administered prolongs life and is to be preferred to all other methods. For producing such a fistula Witzel's method

is to be preferred to Frank's, since a more permanent result is obtained thereby. Non-malignant stricture of the œsophagus is more suitable for operative treatment than the malignant form. Here dilatation and the radical operation, either singly or in combination, are the procedures to be adopted. If an artificial fistula is necessary Frank's method is to to be preferred to Witzel's, since a permanent fistula is not required and Frank's method gives good immediate results. Furthermore, it is the much more simple method. After the stricture has been made pervious and dilatation is going on the latter may be performed by the patient himself after he has gained a little experience. Thus dilatation may be continued as long as necessary without the patient becoming dependent upon a physician's attendance.

Treatment of Labor in Women with Contracted Pelves, as Such Cases Are Met with in Private Practice.—A. Mueller considers the following methods: (1) The Induction of premature labor; (2) Prophylactic version; (3) High forceps; (4) Symphyseotomy; (5) Cæsarean section. The induction of premature labor is, of course, only available when the case comes under consideration during pregnancy. In multipara the histories of previous pregnancies give great aid in deciding the advisability of inducing premature labor. In all cases, however, frequent estimastions should be made between the size of the head and that of the pelvis and the induction of premature labor affirmed or negatived in accordance therewith. In primipara such estimations constitute the sole criterions for the decision of this question. In all cases in which the pregnancy is allowed to proceed the patient should be put as early as possible upon a strict "diet cure." When labor has begun the advisability of so-called prophylactic version is first to be considered. The author's experience shows that as a rule marked success attends this procedure. Of 107 cases thus treated the results for the child were as follows: 90 lived over 8 days, 13 died within 8 days, 4 were dead before the version was performed, and in 10 perforation of the after-coming head was necessary. The primary requisites for the successful performance of version are (1) a lax uterus and (2) skill and dexterity on the part of the obstetrician. The chances for the child are materially increased if a short pause is made between the completion of the version and extraction. If version is contraindicated or the time for its performance is passed, high forceps is next to be considered. This procedure is not nearly so dangerous for either the mother or the child as is supposed by many. Great force may frequently be used without material damage being done. High forceps should always be tried before perforation, symphyseotomy or section are resorted to. If both version and high forceps are unavailable symphyseotomy or Cæsarean section can alone save the life of the child. The former, which ten years ago was so popular, has latterly fallen into disrepute since extended experience has shown that the results obtained are unsatisfactory. Cæsarean section is seldom advisable in private practice, and if such is to be performed the patient should, if possible, be removed to the hospital. The summary of the procedures advised is as follows: during pregnancy—"diet cure" and premature labor. When labor has set in—prophylactic version or high forceps. If these fail, perforation, unless especial weight is to be laid upon saving the child, when Cæsarean section or rarely symphyseotomy may be done.

French Journals.

Contribution to the Study of the Central Origin of Lead Paralysis.—Philippe and de Gothard have examined histologically, the brain of a patient, who since 1893 has had numerous attacks of lead paralysis. In the last two years the ameliorations became more and more incomplete, and finally amyotrophic paralysis became definitely established, especially marked in the extremities. The dominant lesion was a subacute poliomyelitis, developing without meningitis. The nerve lesions were, histologically speaking, of the purely secondary order, and degenerative. This observation demonstrates the possibility of the central origin of certain forms of lead paralysis, notably of the generalized and amyotrophic form.—*La Presse Médicale*, January 28, 1903.

Bony Ankylosis of the Elbow-joint Consecutive to Gonorrhœal Arthritis.—M. E. Foisy reports this case. The patient was a man twenty-three years old. He was suffering from an attack of gonorrhœal arthritis of the left elbow. There was redness and swelling of the part and excruciating pain. The arm was almost in extension. After the acute attack, which lasted about a month, the arm was put up in plaster, under chloroform. The arm was flexed to an acute angle. The plaster was left on for six weeks, after which the arm was massaged till a slight degree of mobility of the elbow was attained. But little by little the power of movement diminished, and for a year the elbow was completely ankylosed at an obtuse angle, the forearm in demi-pronation. The movements of flexion and extension, as well as of pronation and supination were abolished. Resection of the elbow was practised, and the bones at the elbow were found completely fused. There was even bony fusion of the head of the radius and the superior extremity of the ulna. The rapidity with which this ankylosis took place was remarkable.—*Bulletins et Mémoires de la Société Anatomique de Paris*, October, 1902.

Bronchopneumonia of One Lung and Gangrene of the Other, Caused by a Large Pin in the Bronchial Tube.—Courmont and André have recently observed a young man who had swallowed a long pin with a glass head. He applied first to the department of surgery and radiography, but nothing was discovered there. Nevertheless, one day the foreign body appeared at the neck. An attempt at extraction was fruitless, and it dropped lower down into a bronchial branch. The symptoms of infection rapidly developed bronchopneumonia, pleurisy, hyperthermia. The general condition was grave, the pulse rapid, and death supervened. At autopsy the pin was found head down. This had fallen into the left bronchus, obstructing the openings of all the bronchi supplying the inferior lobe. This fact explains the development of bronchopneumonia of that lobe. Corresponding to all the obstructed area. The point was fixed a little below the bifurcation in the right bronchus; a small gangrenous focus had developed at this point. The pin was firmly embedded and extraction had been impossible.—*Lyon Médical*, January 18, 1903.

Bulletin of the Johns Hopkins Hospital, February, 1903.

The Clinical Value of Blood-pressure Determinations as a Guide to Stimulation in Sick Children.—Henry Wireman Cook closes his paper by saying that although it must not be inferred that blood-pressure observations are considered the only measure of a patient's condition, or that any single observation necessarily gives an absolute indication for treatment, still, in general, it would seem that blood-pressure observations which constitute a numerical index for the mechanism most affected by stimulation would be the best single guide to the choice and administration of stimulants. The blood-pressure of children is a far more absolute quantity than in the adult when arteriosclerosis and great differences in musculature have to be considered. Some of the results noted are: Alcohol in repeated doses appears to have a marked and permanent beneficial effect. It does not seem to be indicated where urgent stimulation is required, while very useful in a depressing toxic or marantic illness, where, besides its doubtful stimulant action, it is of value as a conserver of energy in the nature of a food. Strychnine is found to have a more positive effect on the blood-pressure. Digitalin hypodermically, in equal doses, acts more quickly and produces a higher rise in blood-pressure, but the elevation is not maintained for so long a period. Infusions of normal saline solution are found unsatisfactory for any true stimulant effect, though they seem useful in some toxic and wasting conditions.

The Results of Some Observations on Blood-pressure in Morbid Conditions in Adults.—John Bradford Briggs concludes from the results of the same treatment in two cases, in one of which the blood-pressure was abnormally low, and in the other markedly raised, that the digitalis drugs are not necessarily bound to raise the arterial blood-pressure. In both of these patients the blood-pressure returned to normal limits. The treatment was digitalis, rest in bed, and free purging. A modified Riva-Rocci instrument was used to measure the blood-pressure in the cases studied. The effects of alcohol on the pulse were never marked. The total effect of alcohol on the vasomotor system is depression. The rise in blood-pressure produced by tincture of capsicum was not followed by any fall, as in the case of whiskey. Strychnia hypodermically, in moderate doses, was found to cause a rise in pressure somewhat delayed as compared with that after alcohol, but continuing with more steadiness, and lasting from one to three hours. A similar rise in blood-pressure with more rapid onset and somewhat less permanent, followed the use of digitalin. Subcutaneous infusions of normal saline solutions have no stimulant effect on the pulse. Results show that it is useless to infuse with any idea of filling up the depleted vessels; the solution is excreted probably as rapidly as it passes into the circulation. In surgical and traumatic shock, saline infusions are absolutely contraindicated. But cases of pure shock uncomplicated by the severe symptoms of hemorrhage, or with those symptoms superadded, will often respond to the true cardiovascular stimulants by prompt and steady increase in the blood-pressure. Strychnia and digitalin seem to meet the first indication in many cases of shock.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held February 19, 1903.

ANDREW H. SMITH, M.D., PRESIDENT.

Action on Proposed Resolutions.—Dr. ALFRED MEYER offered this resolution, which was carried: "*Resolved*, That, in view of the inadequate provision for the care of the consumptive poor of the State of New York, the New York Academy of Medicine endorses the efforts of the State for the establishment by it of a hospital for incipient cases of tuberculosis. *Furthermore*, That it deplores the insufficiency of the appropriation for, and the delay in opening the institution at Bay Brook, three years having elapsed since the initial appropriation; and *Furthermore:* That it would urge upon the Governor and Legislature adequate moral and financial support of the Board of Trustees of this institution, in order that their work may redound to the credit of the State of New York; and *Furthermore*, That a copy of these resolutions be forwarded to the Governor and all State officers and to all members of the Legislature, duly signed by the President and Secretary of the New York Academy of Medicine."

Dr. S. A. KNOPF offered this resolution, which was carried: "*Whereas*, Strenuous efforts are being made to induce the Legislature to undo utterly the great advances made in recent years in tenement-house reform and sanitation, and to prevent the permanent carrying into effect the great improvements in the construction and management of tenement-houses in New York and Buffalo, which have been made possible by the recent tenement-house law, and *Whereas*, Pulmonary tuberculosis is extremely prevalent in the city of New York, there being eight thousand deaths and twenty thousand cases annually, and *Whereas*, The lack of light and air in the rooms of the great masses of the people is one of the most potent causes in increasing the prevalence of this and other communicable diseases, and constitute serious menaces to health and morality, be it *Resolved*, That the New York Academy of Medicine deplores any weakening of the present tenement-house laws, and urgently requests the Legislature to permit no changes to be made that will in any way decrease the amount of light and air available for the people living in such houses, or in any way take a backward step in regard to their sanitary condition.

Radio-praxis (with Special Reference to the Ultra-violet Rays; Demonstration, etc.)—Dr. H. G. PIFFARD read this paper. (See page 361.)

Dr. WILLIAM S. GOTTHEIL said the subject was one that he had devoted much attention to during the past two or three years. In order to obtain results in the deeper-seated processes, he said that we should get penetration, and this could only be had by amperage. He referred to certain experiments which he had conducted with Dr. Franklin, and which were published in the MEDICAL RECORD, April 19, 1902, in which the following deductions were made: (1) Light, in proper concentration from a source of sufficient actinic power, can be made to penetrate the entire thickness of the human body, including both surfaces of the skin; hence all the internal are accessible to its influence. (2) Since no portion of the body, however, can be more than half the thickness of the frame from the cutaneous surface, and much of it is closer, the time required for efficient actinic penetration to any depth is only a fraction of that employed in the experiments; and, conversely, if the time employed is equal, the chemotaxic effect will be far greater. (3) The proof of the penetration of actinic light to and through the internal organs apparently opens a field for its successful employment as a therapeutic agent in internal maladies, in view of its admitted efficacy in a number of external affections.

Dr. J. MOUNT BLEYER said that he had made a study of light with special reference to its therapeutic value for fourteen years. He had used both the arc and the sunlight, the ordinary method being the search light. With this light, in a certain proportion of cases with cavity formation, his results had been astonishing. Those patients who could not afford to take this treatment at home he had advised to go to Coney Island, or some similar resort, and there expose themselves in a practically nude condition, lying down in the sunlight for three or four hours. These patients did equally well as those who had the arc light used.

Dr. GEORGE G. HOPKINS of Brooklyn differed with the reader of the paper in his statement that ice did not interfere with the blue rays but that water did. He said that one fact Finsen demonstrated was that the blue, the ultra-violet and the violet rays would pass through water. Some rays were intercepted by a solution of alum; this would cut off the red, green, and orange rays. He had great difficulty in obtaining non-foggy lenses in this country. The Finsen light was an admirable hæmostatic and had given him excellent results, especially in cases of cancer of the cervix uteri; in such cases the hemorrhage had been controlled quickly. A great objection to the Finsen light was the necessity for long exposures. A very strange thing to him was the apparent inocuousness of the horny layer of the skin to the *x*-ray. The worse cases of gangrene he had ever seen had begun below the skin, which was healthy.

Mr. GEORGE B. PEGRAM presented two small viols of radioactive substances that had been obtained from pitchblende, sold at $4.50 a gram by a firm in New York. The radiation from such substances was not homogeneous. A large fraction of the total radiation could be intercepted by even a very thin screen of aluminum foil or other substance, while each successive layer of foil had less and less proportionate absorbent effect. Other things being equal, the absorption of the radiations by a substance was about proportional to its density. Professor Rutherford had recently detected the presence, in the radium and thorium radiations, of a very small percentage of rays that could penetrate several centimeters of solid lead. He said that the surface of bodies could be made temporarily radiative by placing them in the air near radium or thorium compounds, which effect would be greatly increased if the bodies exposed were kept at a high negative potential. A platinum anode used in the electrolysis of thorium solution became strongly radioactive. The wide distribution of radioactinic phenomena in nature was shown by the fact that a negatively charged wire suspended in the atmosphere for several hours became radioactive. By rubbing the wire with a piece of leather the activity could be made to effect the leather, being simply transferred. The mass of evidence at the present time proved that the greater part of the penetrating rays from radium are quite similar to the cathode discharge in our *x*-ray tubes, consisting of negatively charged particles shot off with a velocity comparable to that of light. These radiations could be deflected by a magnet, while *x*-rays, being ether vibrations, were most influenced in the direction of the magnetic field. He said that the various recent statements in the daily press, that the maximum amount of radium in the universe was only 2 kg. could hardly be taken seriously, though it was greatly to be hoped that a less expensive source of radium than pitchblende would be disclosed.

Dr. MILTON FRANKLIN thanked Dr. Piffard for his excellent paper in which he found nothing with which to disagree. He said that if you were to accept as true all the reports that we had heard of the ultra-violet treatment either the light ray and the heat ray or imagination was a potent factor in the process, because the majority of operators had obtained their results with apparatus totally innocent of any ultra-violet rays. He had experimented with some of the largest arc lamps that had been made, and in one instance had exposed the flexor surface

of his arm to the concentrated light of a 100 ampere arc lamp for a space of from twelve to fifteen minutes for four days in succession, without the slightest reaction, while a number of men using apparatus of the same type and much smaller, had claimed cures of really obstinate cases. Personally he thought that the element of suggestion on the part of the operator, as well as on that of the patient, was unduly potent. Of all the forms of low-tension arcs, that of Finsen was the most rational as regard the position and number of collecting lenses. The essential light from an arc came from a depression in the positive carbon known as the crater. This crater he had found from a number of measurements approached the general shape of a parabola, whose abscissa lay in the line from the center of the positive carbon to the nearest point on the negative carbon. Now the light emanating from an illuminating surface was not uniform in all directions, as might be supposed, but as was proven at the end of the eighteenth century by two investigators whose names had slipped his memory, it was of the greatest intensity at a direction perpendicular to the surface, and decreased as the cosine of the angle of obliquity in any direction. At this rate there would be no rays from the crater in a direction at right angles to the axis of the crater or in the axis of the ordinates. This was, to a certain extent, overcome by the light from the negative carbon, and from heated portions of the positive carbon outside the crater. Those lamps which had the collecting lens at any distance from the line in which the abscissa of the crater lay were very poorly constructed. The Finsen lamp had the negative carbon in a position which insured that its axis coincided with that of the positive carbon, so that the light had its greatest intensity in a direction corresponding with the coincident axes of the carbon. In this way, by bringing the collecting telescope into a line as near to the axis of carbon as possible, and by multiplying the number, the amount of light collected was the greatest that might be obtained.

The distinction between what was called heat light and chemical rays was very crude, as all the effects that had been ascribed to one class might be performed by the other. Thus chemical action was produced even by the heat rays, as instanced by the experiments by Abney, in which he photographed a hot kettle in an absolutely darkened room by the rays that emanated from the kettle. In the same way it might be proven that chemical rays produced light and heat under suitable circumstances, and that the light waves were capable of producing heat and chemical action. For this reason the testing of the ultra-violet light capacity of a generator by means of silver salts was not reliable. In the picture exhibited by Dr. Gottheil, as taken by light that had been transmitted through the body which he made, he wished to say that he never claimed for an instant that the light which was transmitted was of the ultra-violet region of the spectrum, and he was strongly convinced that it was not, but were rays of greater length, as, in the first place, the machine with which they were made did not transmit any ultra-violet light through its glass lenses, and besides he had experimented with every fluorescent substance that he could get, and had found no evidence of the transmission of these rays through the body. It was safe to say that there was at present no known glass which was diaphanous to the ultra-violet, as had been claimed.

He offered an explanation of the peculiar effect produced by the letters shown by Dr. Piffard which were rendered phosphorescent by the *x*-ray on the one hand, and by the ultra-violet on the other. It was noted that the letters had been energized by the ultra-violet rays, and gave off a blue light, and that the picture that it produced was conspicuous for the amount of halation produced, and that the density was not very great, while the letter that had been exposed to the *x*-rays, gave a white phosphorescence, and the picture produced was almost free from halation and quite dense. He suggested as explanation that the rays emitted by the ultra-violet energized letter were of such nature that they were reflected by the glass of the plate, and caused halation, while the *x*-ray energized letter, emitted such light as was readily transmitted by glass. The color of the reflected light suggested the feasibility of the explanation of an apparent photographic paradox. A great drawback to the general use of low-tension arc was the small focal area of the light, which was generally less than three-quarters of an inch, while in the little lamp shown by Dr. Piffard, the area covered might be increased to any size that was desired. The limit would not be in the size of the lamp, but in the size of the lesion. He had recently made some tests of the farthest position at which ultra-violet rays would fluoresce by means of a reflecting diffraction-grating, and if the rays were in the same relation as regards length as the rays lower in the spectrum, it would not be difficult to compute their wave lengths.

In answer to Dr. Piffard's remarks as to the action of the green rays, he begged to state that in the conclusions of Chastaign, which covered all the chemical actions of light up to about the middle of the last century, it was assumed that the action of the rays down to the green was reducing, that the action of the rays below the green was oxidizing, and that there had never been found any action of any kind in the green. The action of the oxidizing rays were extremely weak on the animal organism. The remark of Dr. Gottheil, that amperage was required to obtain penetration was an error. The energy of any current was measured by the product of the potential by the amperage, and the energy in the small static spark was very great. The statement of Dr. Piffard, that water absorbed the ultra-violet rays while ice did not, to which Dr. Hopkins took exception, might be answered in a few words: Water contained air in solution, and in exact proportion to the amount of this air did it absorb the chemical rays, while the air in ice was separating in fine masses or globules which did not appreciably interfere with the passage of the rays. The supposition that the effect of the *x*-ray was produced by the projection of minute masses of platinum into space with infinite velocity had been disproven by Gilchrist, who sent a section of skin from a very severe burn to Professor Abel for chemical analysis, and the report showed that there was no platinum in the skin.

SECTION ON MEDICINE.

Stated Meeting, Held February 17, 1903.

JAMES K. CROOK, M.D., CHAIRMAN.

Medical Chart for Office Patients.—Dr. FREDERIC GRIFFITH presented a chart, which was intended for walking cases, not only enabling a fuller record to be kept in th isway, but creating a favorable impression in the mind of the patient.

The Holmes Sanitary Tent Cottage.—Dr. JAMES CROOK exhibited a model of a combination tent and cottage devised by Dr. A. Mansfield Holmes of Denver, Col., and used by him in the sanatorium treatment of tuberculosis. After describing the construction of the tent, Dr. Crook stated that he had compared it with other structures of the kind in use, and thought the Holmes' tent presented several points of advantage. Possessing as it did a substantial timber floor, as well as wooden walls halfway up to the eaves, the cottage had a very secure foundation, which was a guarantee against dampness from the ground and a protection from the inclemencies of the weather. The excellent ventilation afforded by the tent, and its ready convertibility, during mild or hot weather, into a tent pavilion, were very desirable features. The tent cottage could be manufactured at a cost which would place it within the reach of persons of slender resources. Furthermore, its construction was such as to admit of the easy detachment of its component parts and packing in a small compass for transportation. Dr. Crook hoped to see the tent-cottage come into general use, not only in the treat-

ment of tuberculosis, but in hospital work generally when isolation was desirable.

Symposium on Brochopneumonia.—This comprised presentation of the following papers:

Etiology.—Dr. Lewis A. Conner presented this phase of the subject. He prefaced his remarks by restricting the term bronchopneumonia to an inflammation beginning in and confined at first to the walls of the bronchi. As a matter of fact, the term, he said, described a lesion rather than a disease. The cases of bronchopneumonia were divided into two great classes, primary and secondary. Of a large number of cases occurring in children, Holt found 37 per cent. were primary, whereas in another large series occurring in adults, 92 per cent. were secondary. According to Holt, 97 per cent. of the cases of bronchopneumonia occurred in children under three years of age. It was especially frequent among the children of the lower classes, and, in general, among poorly nourished, and particularly rachitic, children. Among the acute infectious diseases giving rise to secondary bronchopneumonia were measles, influenza, diphtheria, whooping cough, and scarlet fever, and of these measles easily stood first. While the proportion of cases of measles complicated by bronchopneumonia varied a good deal with different epidemics, it was not uncommon in hospital practice to find such complication in as many as forty or fifty per cent. In private practice, and under good conditions, the percentage was not nearly so large. Aspiration pneumonia was found in all conditions of stupor and unconsciousness in which the normal sensitiveness of the larynx and trachea was lost, and the act of swallowing was difficult or imperfect. The bronchopneumonia which so frequently developed after submerging belonged to this class, and, although somewhat different, the bronchopneumonias arising from the inhalation of ether, illuminating gas, and smoke really belonged to the same class.

Pathology.—Among the cases of primary bronchopneumonia the bacterium most frequently found was the diplococcus of pneumonia. In considerably over half the cases this organism was found either alone, or in conjunction with other germs, most commonly, the streptococcus. In the bacteriology of secondary pneumonia, the same organisms were found, and, in addition, the bacillus of diphtheria, the bacillus typhosus, and the bacillus intracellularis meningitidis. The early investigators were inclined to believe that secondary bronchopneumonia was not the result of the specific bacilli of the infectious diseases with which it was associated, but rather of other microorganisms found present at the same time. Modern methods of investigation had changed this view. For example, it had been shown that in 62 cases of diphtheritic pneumonia, the Klebs-Loeffler bacillus was found in 90 per cent., and in 12 of the cases was the only organism present. Pfeiffer had shown that in persons dying of influenza pneumonia at the height of the disease, the influenza bacillus could be obtained from the affected area in pure culture, whereas in persons dying at a later stage streptococci and pneumococci were more apt to be found. In one series of 19 cases of bronchpneumonia complicating typhoid fever, pneumococci, streptococci, staphylococci, and the bacillus of Friedlander were found, but in none was the bacillus typhosus obtained from the lungs. It was now believed by many that the bronchopneumonias occurring in conjunction with tuberculosis were commonly due to pneumococci or streptococci, and that the tubercle bacillus was only responsible for the caseation which so often followed this disease process. Aspiration pneumonias, as a class, had not been studied bacteriologically, but there was no reason to suppose that the bacterial flora differed materially from those already considered. The question as to whether or not the bronchi in health contain pathogenic bacteria had not yet been definitely settled, but it was probable that they were not found in the bronchi under normal conditions.

The Diagnosis.—Dr. Charles E. Quimby read this paper. He said that the term bronchopneumonia was now used to cover conditions which were formerly embraced under the term capillary bronchitis. This was justified by the fact that many similar cases were met with in which the pneumonic factor was very prominent although in many others it was not a marked feature. The diagnosis of bronchopneumonia implied essentially not the recognition of the fully developed condition, but the determination of the point at which the bronchitis passed into a pneumonia—in other words, when the mechanical disturbances of bronchitis began to interfere materially with respiration. He believed that the earliest stage of the transition, when it developed uniformly throughout any considerable portion of the lung, was indicated by a drop in the pitch of inspiration, nearly, if not quite, to that of expiration, and the retention of a distinct vesicular quality of the respiratory sound. The drop in the inspiratory pitch was due to the inclusion of the shorter bronchioles; the diminution of intensity was dependent upon the plugging of the tube and inclusion of air without definite pulmonary consolidation. The retention of vesicular quality depended upon patency in some of the tubes, and its amount varied with the proportion of tubes involved. From this point the change to definite pulmonary consolidation was evinced, not by change in the pitch of respiration, but by a gradual enfeeblement of the vesicular element and its replacement by a tubular quality. Percussion and palpation at this time were both unreliable, nor was there any change in the attendant râles which could be certainly appreciated or necessarily ascribed to the advancing pathological process. Some time might elapse before any other evidence of advance of the pneumonic process was forthcoming, but after a time a change in the sputa and an increase in the temperature and in the respiration rate would confirm the first suspicions of pneumonia. Variations of respiration were apt to receive too little attention in this disease. He believed that the slightest *persistent* increase of respiration following a uniform respiration rate should always lead one strongly to suspect a beginning pneumonia. It was impossible to distinguish a simple bronchopneumonia from an ordinary tubercular pneumonia by the physical signs, though this differentiation could be made by examination of the sputum and attention to the history. The differentiation between bronchopneumonia and lobar pneumonia was seldom difficult. In recent years he had seen a condition which was liable to lead to some confusion. This was a localized hyperæmia developing in acute influenza, and associated, perhaps, with a slight degree of hypostatic congestion. It was usually observed at the back, was sudden in its onset, and often sudden and quite erratic in its disappearance. He was of the opinion that the condition was very largely of vasomotor origin. In conclusion, he would say that the diagnosis of bronchopneumonia was often a matter of inference rather than of demonstration.

The Treatment.—Dr. William H. Thomson discussed this part of the subject. He said that lobar pneumonia and so-called bronchopneumonia were widely different diseases. The former had a distinct, specific invasion as a primary cause, and the chief danger was toxæmia. For this reason his prognosis in such cases was based more upon the presence or absence of evidence of toxæmia than upon the apparent extent or severity of the local process in the lungs. On the other hand, bronchopneumonia was a part of the bronchitis, and the one great danger from beginning to end was suffocation, and not toxæmia. It was important to keep in mind the fact that one was dealing with a mechanical element. In his opinion, it was the duty of every physician to endeavor to treat every case of bronchitis in such a way that it would remain a bronchitis. In the majority of cases of bronchitis there was no infection. It had been demonstrated to his satisfaction that the entire repiratory tract was sterile except in

cases of accidental infection. Repeated experiments had failed to show the presence of the tubercle bacilli in the air expired by a patient suffering from tuberculosis so long as there was no contamination from expectoration. Lister had long ago called attention to the fact that when the pleuræ were filled with air as a result of an injury from a fractured rib that the surgeon need not fear empyema because this air had been filtered and freed from bacteria by the lungs. The physician should prevent the downward spread of bronchitis by treatment directed toward securing a sufficient fluidity of the secretions. The first and last practical indication, therefore, was to make everything in the bronchial tubes so fluid that it could be most easily expectorated. He thought that, in the great majority of cases, bronchitis was a nervous trouble, and was brought about by a chilling of a portion of the surface of the body. It should be remembered that the arterial supply of every viscus of the body was under the control of nerves which were directly connected with the skin immediately over these viscera. There were also certain special relations. The arterial circulation of all internal viscera was affected at once through the vasomotor system by impulses traveling from the body surface. It had been shown experimentally that the shutting off of the arterial supply from the kidney of a dog for forty minutes so damaged the renal cells that albuminuria persisted for twenty days. It was easy, therefore, to see that any chill to the surface of the body reflected so as to produce an ischæmia in a viscus in relation with this area, was likely to damage the cells of this viscus. This was his notion of "catching cold," and it threw light upon the causation of bronchitis. Bronchitis was, therefore, often directly the result of a chilling of a portion of the body surface, and consisted in a catarrhal inflammation of the bronchial mucous membrane. The bronchioles were without cartilage, and as they approached their terminals they were nothing but thin membranous tubes with very few muscular fibers as compared with the larger bronchioles. When a main bronchus became plugged by a foreign body, a violent inflammation of the bronchus resulted, but this was nothing compared with the serious and rapidly destructive changes occurring in all parts of the lung tissue supplied by that bronchus. Very rapidly the area in those lobules was absorbed, and the lobules collapsed, and, following close upon that, an intense inflammation developed, and permeated all of the lobules and filled the air cells with an exudation from the blood, including lymphocytes and pus cells. The bronchioles were so constructed that they could tolerate nothing but air, and any liquid was practically a foreign body there. If in addition to increased moisture, there were plugs of mucus descending, the result was the same as a plugging of a main bronchus, only on a much larger scale. According to this theory, bronchopneumonia had a mechanical course, *i. e.* the tubes were closed by the secretions of a bronchitis. The transition from bronchitis to bronchopneumonia was almost surely indicated by a marked rise of temperature, and from the very nature of the process it was evident that there would be no crisis, and that the disease might last for a very long time.

The first indication for treatment was to make the secretions as fluid as possible. For this purpose there is nothing better than the internal use of oils, and, preferably, linseed oil. This should be kept up all through the disease, bearing in mind that plugs of mucus were constantly present in the larger tubes, and acted as valves. It was undoubtedly because of this pumping action that many lobules were deprived of their air, and were made to collapse.

Varieties of Cough.—Coughs could be divided into two great classes, the irritant and the expectorant. The first was useless and mischievous, and was well observed in cases of pleurisy. Its sound was distinctive, there being separate hacks like the blows of a hammer, each hack being independent of the others. In a child, this irritant cough was squeaky. The expectorant cough was known by the fact that each effort at coughing was linked to the others, and the process continued until expectoration was produced. For the irritant cough anodynes were beneficial; for the associated constriction of the bronchi, the asthmatic element, belladonna should be given in full doses. The original cause being mechanical, he believed it should be dealt with by mechanical means. By this he meant that the patient should be frequently placed with the head downward, the ribs compressed with every act of expectoration and, in short, every effort made to aid respiration. This treatment should be aided by the usual external applications, one of the best of which was the old embrocation composed of a teacupful of vinegar, a teaspoonful of turpentine, and the yolk of an egg. In the case of an adult very great improvement often followed the free use of a number of blisters to the chest.

Dr. Louis Faugères Bishop said that many authorities expressed the opinion that the colon bacillus was a cause of bronchopneumonia, and that many children became ill with this form of pneumonia as a result of self-infection. We were still unable to say anything very definite as to the possible tuberculous origin of many bronchopneumonias.

Dr. William L. Stowell said that there were in this city annually about six thousand deaths from pneumonia, and fully three-fourths of these were bronchopneumonias. A large number of infants under two years of age succumbed to this disease. It was well to remember that all of the infectious diseases of childhood might be complicated with bronchopneumonia, and in view of this fact to caution the parents and the nurses regarding the grave consequences of paying too little heed to these common ailments of childhood. Of late years his treatment for bronchopneumonia in children had been practically the same as for bronchitis, except that if the temperature range was high measures were taken to control this high fever. If the temperature rose to 103° or 104° F., the pulse was rapid and large areas of lung tissue were involved, he was accustomed to prescribe tincture of aconite and sweet spirits of niter, although in older and more robust children he did not hesitate to make use of small doses of phenacetin or acetanilide. There could be no doubt that oils were very useful in both bronchitis and bronchopneumonia. He was accustomed to prescribe for children of from one to three years of age a mixture of equal parts of castor oil, syrup of rhubarb, mucilage of acacia, and paregoric. Although this prescription seemed to contain too large a proportion of paregoric, he found that practically it worked very well, probably because it kept the secretions loose. He was in favor of the use of embrocations in children, and preferred for this purpose to use the oil of camphor—not camphorated oil. Steam inhalation was often most useful. Old persons with bronchopneumonia were apt to have also chronic bronchitis, and asthma, and hence he found Hoffman's anodyne with glycerin or with tincture of cardamom a very useful remedy. The old-fashioned cough syrups were apt to disturb the stomach. For both the old and young sinapisms and mustard poultices were useful. He avoided alcoholic and other cardiac stimulants in infants as far as possible, except strychnine. The latter he gave in doses of $\frac{1}{300}$ of a grain to young children, and in doses of $\frac{1}{30}$ of a grain to old people.

Dr. Godfrey R. Pisek spoke of the wide variations in the statistics of bronchopneumonia collected from private and hospital practice. In this city there were 2,500 deaths from bronchopneumonia, of which about 2,000 were in children under five years of age. The previous condition of the patient exerted an important influence upon the course of the disease in hospitals. Children who were rachitic or who had been poorly fed were poor subjects for bronchopneumonia. In the Babies' Hospital last year many of the gastroenteric cases developed bronchopneumonias, but after separating the severe cases of gastro-

enteric infection from the milder ones the disease was controlled. Dr. Quimby's remarks on the physical diagnosis were most interesting, but it seemed to the speaker impossible to draw such sharp distinctions in children. The diagnosis here must rest mainly upon the results of auscultation. Dr. Thomson had highly recommended belladonna, but, according to his experience, this drug was not well borne by children. Change of position was certainly a most potent means of aiding expectoration, and should never be overlooked in children. These little ones should not be trundled around by their mothers, but their position in bed should be changed from time to time. The mustard poultice was useful in the early stage to relieve pain if repeated at intervals of four hours until the skin over the affected area was decidedly reddened.

Dr. Crook said that he considered vocal fremitus extremely useful, and although a child could not be made to count, one could learn much from vocal resonance while the little patient was crying. He would like to know Dr. Thomson's method of giving linseed oil, and also as to the use of blisters in very old persons.

Dr. Conner said he thoroughly agreed with Dr. Quimby regarding the diminution or enfeeblement of the inspiratory murmur in small areas of consolidation. It was a change of the greatest value in the early stage. The weight of authority seemed to be in favor of considering the presence of the colon bacillus an infection occurring just before death. Theoretically expectorants should be useful, though practically he had derived so little benefit from them that he found himself relying more and more upon external applications, and in the case of adults, particularly upon dry cupping.

Dr. Quimby said that he too was a very firm believer in the mechanical treatment of these cases, and felt that he could point to at least one case in which life had certainly been saved by the inversion of the patient as described by Dr. Thomson.

Dr. Thomson said that linseed oil had been his one remedy for bronchitis for many years. Unfortunately for him four large manufacturers were now making the emulsion and selling it all over the country. There were exceedingly few cases of acute bronchitis that would not yield in a few days to the linseed-oil emulsion. The ordinary druggist found it difficult to prepare this emulsion, but it could be readily done by machinery. In some acute cases he added $\frac{1}{12}$ of a grain of morphine or six or eight grains of chloral to each tablespoonful of the emulsion. With reference to the toleration of children for atropine, he would say that when a young practitioner in medicine had been taught that there was a great difference in the tolerance of children for opium and belladonna, and that children were particularly tolerant of belladonna, and this had since been his own experience. It had been his rule to give the tincture of belladonna in whooping cough until the skin flushed, according to the treatment recommended by Fuller. This would generally control the cough in a week, although there might be a relapse any time in six weeks.

Officers Elected.— Dr. Lewis A. Conner was elected Chairman, and Dr. E. E. Smith, Secretary, of the Section.

A Case of Leukæmia Associated with Tuberculous Mesenteric Glands in a Boy of Three and a Half Years.—George Carpenter reports a case in which there was a family history of tuberculosis. Blood examination showed that there was leukæmia. At the autopsy petechial hemorrhages were found over the surface of the heart; the heart muscle was very soft and pale. The bronchial glands were enlarged and very dark; on section the lungs were somewhat œdematous. The stomach showed some submucous hemorrhages. The intestines displayed unduly prominent Peyer's patches and lymph follicles. The mesenteric glands were very considerably enlarged. They were pale in color and the largest of them were caseating in the center.—*Medical Press and Circular.*

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK

Stated Meeting, Held February 23, 1903.

Charles N. Dowd, M.D., President.

The Importance of Examinations of the Stomach Contents of Patients Suffering from Chronic Gastric and Intestinal Disorders.—Dr. Freeman F. Ward presented a paper with this title. He said that the day had long past when the physician's duty, in a case of supposed stomach disorder, was fulfilled by merely prescribing rhubarb and soda. In every obstinate or intractable case, after making the usual examination of the heart and lungs, the general practitioner should note carefully the condition of the liver, stomach, and bowel. There was a certain inverse relationship between the acidity of the urine and that of the stomach. The urine should be tested for indican, as this gave some idea of the character of the digestive process. At the first test-meal examination the main points to be determined were: (1) The quantity of the food in the stomach; (2) whether or not free hydrochloric acid was present; and (3) whether this acid was present in excess. Too much stress should not be laid upon the presence or absence of free hydrochloric acid in making a diagnosis of cancer. A number of illustrative cases were cited.

The Treatment of Gastric and Duodenal Hemorrhages.—Dr. Max Einhorn was the author of this paper. He said that the diagnosis of these hemorrhages was usually easy. As a rule, there was hæmatemesis, and sometimes melæna, and it was necessary to differentiate in some instances between true gastric hemorrhage and that arising from conditions present in the lungs or throat. The hemorrhages under consideration were apt to be associated with more or less marked dyspeptic symptoms. Small hemorrhages, frequently occurring in cancer and rarely in ulcer of the stomach, usually required no treatment. Larger hemorrhages were generally accompanied by hæmatemesis. Absolute rest in bed and abstinence from food and drink by the stomach, together with the use of medicines to control peristalsis, were indicated. The local application of ice seemed to be useful, as did also the subcutaneous injection of gelatin. Adrenalin had been employed in a few cases with very satisfactory results. The author said he had recently made some experiments on rabbits, which seemed to indicate that by the subcutaneous injection of adrenalin gastric hemorrhage could be controlled. In two cases of gastric hemorrhage he had injected twice daily about 1 grm. of a 1 to 1,000 solution of adrenalin with apparently good result. When surgical measures were demanded because of profuse gastric or duodenal hemorrhage, the bleeding point should be sought for and cauterized, but if it could not be readily located it might be necessary to do a gastroenterostomy.

The Treatment of Benign Stricture of the Pylorus.—Dr. John M. T. Finney of Baltimore presented this paper. He said that it was now generally admitted that it was advisable to operate early in every case when there was reason to believe the existence of a malignant growth, and he would urge a greater readiness to resort to operation in the numerous cases in which the stomach gave out as a result of the strenuous life of the present day. In the fifteen years following the first gastroenterostomy in 1881, 298 cases of that operation were collected, whereas in the next two years this number had been increased to 500. Many surgeons in recent years had reported a large number of such operations. Thus, Mayo had recently reported a series of 107 such operations, done within a period of ten years, with a mortality of only 9 per cent., truly a remarkable showing The speaker thought this operation would in time become as relatively common as the radical operation for the cure of hernia. The cases specially suitable for the operation were those in which there was some interference with the mechanical function of the stomach.

Atony of the muscular coats of the stomach and dilatation of the organ, as well as pyloric obstruction, had been benefited by such surgical intervention. There were many factors arising both within and without the stomach which entered into the production of pyloric obstruction, and in the attempt to overcome it the combined efforts of the physician and the surgeon were more likely to prove successful than the work of either one alone. Medical treatment should always be given a thorough trial before operation, but this having been done it was well to offer the patient the benefits of an exploratory operation without further delay, as this operation would, in the great majority of cases, not only demonstrate the cause of the trouble, but would at the same time afford an opportunity for securing relief. Under the infiltration method exploratory incision was attended by no mortality *per se*. If conditions were discovered rendering further operation necessary, ether could be substituted. He could not subscribe to the opinion often expressed, that, for this purpose, cocaine had no advantages. The mortality in stomach operations had been rapidly decreasing until now it was very low. Pylorectomy had been employed in certain cases of benign stenosis when there was a certain amount of thickening, but the mortality had been so great, 35 per cent. or over, in most instances, that the operation was rarely attempted. It was indicated only when there was an unusual amount of thickening, or when carcinoma was present or suspected. Gastroenterostomy had been employed more frequently than any of the other operations of this class, and was, undoubtedly, the most frequent choice of surgeons at the present day, but to become convinced that it was not ideal one had only to study the reported cases. The steady decrease in the mortality from this operation entitled it to consideration whenever operation was to be advised, even though the results, as regards symptoms, were not always what was to be desired. Vicious circle was found in 38 out of 550 cases reported in the literature, and although many efforts had been made to obviate this the problem had not yet been solved. Mayo had had considerable success in this field, and insisted upon the great importance of securing low drainage by an anastomosis at the most dependent part of the greater curvature. Attention to the proper length of the jejunum above the anastomosis aided materially in preventing vicious circle. The fact remained that an outlet at any other point than the pylorus was contrary to nature. With this idea in mind, Dr. Finney said he had devised an operation, known as pyloroplasty. He had been able to collect twenty-nine cases operated upon by this method, with a mortality of 6.8 per cent. The advantages of this method were: (1) The ease and facility with which it could be performed; (2) its low mortality, 6.8 per cent.; (3) its success in relieving at once the disagreeable symptoms; (4) its applicability, even in the presence of dense adhesions about the pylorus; (5) except in cases of extreme dilatation it furnished effective drainage, placing the outlet at or on a level with the most dependent portion of the stomach; (6) it prevented absolutely spur formation and the vicious circle; (7) it placed the new pylorus in approximately its proper place. The disadvantages which had developed so far were theoretical rather than practical. In one case the mesentery was so short that the apposition of the stomach and duodenal walls was rather difficult. It was conceivable that the adhesions around the new pylorus might cause in time a second obstruction, but there was as yet no evidence that this ever occurred. The operation admitted of the excision of a large portion of the anterior gastric wall, as well as of the pylorus, and the opening could be made so large as to greatly lessen the fear of subsequent cicatricial contraction. There had been a singular freedom from post-operative nausea, vomiting, and pain in his cases.

Dr. B. Farquhar Curtis said he did not believe gastroenterostomy should be done in carcinoma of the stomach unless pyloric obstruction were present. While no doubt, cocaine anæsthesia was perfectly feasible, he felt that the limitations for exploratory laparotomy should be rather strict, and that many persons would reach an untimely end by the effort to verify a diagnosis by an exploratory laparotomy or the attempt to relieve an incurable condition. In these cases of malignant disease exploratory laparotomy would always have a tolerably high mortality. While adrenalin would certainly control hemorrhage when applied locally, its use subcutaneously did not appear to him physiological, because it was well known that when used in this manner it caused a rise of arterial pressure, and so would be apt to increase the tendency to hemorrhage. Therefore, for gastric hemorrhage, he would advocate the use of adrenalin by the stomach rather than subcutaneously. Among the benign conditions which could be relieved were those of hyperacidity and spasm of the pylorus, and a certain class of cases in which there appeared to be a congenital narrowing of the pylorus. In the last-named class the tissues about the pylorus were not thickened, and yet the pylorus itself was so narrow that at operation the tip of the little finger would enter it with difficulty. It might be assumed that for a time this narrowing was compensated for by hypertrophy of the walls of the stomach, or by an unusually vigorous digestion, and that later in life when digestion naturally became somewhat impaired, symptoms arose as a result of this narrowing of the pylorus. He felt that gastroenterostomy was much more dangerous and difficult than pyloroplasty, and the latter operation appeared to him a very great advance in surgery.

Dr. H. Lilienthal reported a case in which he had performed pyloroplasty. The patient was a woman of twenty years, who had suffered for three years previously from epigastric pain after meals. A short time before admission there was vomiting of food and of blood. The girl improved for a time under rectal alimentation, but the symptoms having recurred the operation was done on April 26, 1902. The woman had been completely cured, and had remained so. In this operation there was no tension whatever, and it could be performed very easily in the presence of dense adhesions. In his patient there was found a very small pylorus, apparently of the congenital variety referred to by the last speaker.

Dr. Einhorn said that he had met with several cases presenting the macroscopical appearance of malignant disease of the pylorus, and yet the true condition proved to be one of simple fibrous hypertrophy. He had also met with several cases of tumor of the stomach, which had completely disappeared under antisyphilitic treatment. He would not urge operation too freely for persons with benign stricture of the pylorus because there was still a considerable mortality attached to these operations; he would not advise surgical intervention in this class of cases except for patients who could not get along on a fluid diet. In early obstruction of the pylorus many cases improved so much after having been placed upon a liquid diet for a time that they were able to live in comparative comfort for a long time, even on semi-solid diet. Nor could he agree with Dr. Finney that when the case failed to progress under medical treatment a surgical operation should be done. He recalled three cases in which gastroenterostomy had been done, and the patients had subsequently sought relief for hyperchlorhydria; hence, gastroenterostomy could not be considered a cure for this disorder of the stomach. He had recently seen three cases of duodenal hemorrhage, in each of which the bleeding was so profuse as to endanger life. In such cases a prophylactic operation should be undertaken in the interval between these hemorrhages. He fully agreed with Dr. Curtis that the physician should be careful not to allow his enthusiasm to exceed proper bounds, and permit him to lightly advise exploratory laparotomy. There was altogether too much of this kind of operating at the present day, done apparently

largely with the object of satisfying the curiosity as to the exact condition present.

Drug Substitution and Adulteration.—On motion of Dr. Frank Van Fleet, the Society adopted a resolution endorsing the efforts now being made to expose and bring to justice certain dealers and manufacturers who substitute cheaper and inferior drugs, and pledging to the health authorities the support of the Society in this matter.

Tenement-house Legislation.—The Society also adopted resolutions, similar to those already passed by a number of other medical societies, urging the Legislature to prevent any tampering with the present tenement-house law.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, Held February 16, 1903.

Alexander Lambert, M.D., President.

Ectopic Gestation with Beginning Hœmatocele.—Dr. George Tucker Harrison presented this specimen, which he considered interesting from the fact that the tube had been ruptured, whereas in most cases of ectopic gestation a tubal abortion occurred without rupture.

A New Method of Fixation of the Movable Kidney.—Dr. W. Gill Wylie read this paper. He said that an abnormally movable kidney in women was very common. This was largely due to imperfect development caused by insufficient exercise, especially among the well-to-do classes, and by tight corsets and waistbands, which pressed upon the lower ribs and prevented the proper use of the abdominal muscles. Many of these women presented also a relaxed and congested condition of the generative organs. These cases were usually treated for chronic dyspepsia, but if a careful search were made, a diseased appendix might frequently be found. The displaced kidney probably did not cause the inflammation of the appendix, but if the kidney descended low enough to press upon the appendix, it would cause pain. In many of these cases, removal of the appendix, even if the kidney were not replaced by operation, would relieve the pain and dragging sensation, and the patient would regain flesh and strength. Before the surgeon operated to restore the kidney to its normal position, he should make sure that it really was the kidney, and not the appendix, or some other abdominal or pelvic organ that was causing the pain. Dr. Wylie considered the efforts of many surgeons actually to *fix* the kidney at the level of, or just below, the twelfth rib, as wrong, for the kidney was normally somewhat movable. Moreover, if fixed at this level the tight corsets and bands would press on the kidney and cause pain and discomfort. His aim was to replace the kidney in its proper position, and then suspend it in such a way that it would move slightly with respiration, as it should in health. This was accomplished in the following way: The incision was made just below the twelfth rib, and the kidney replaced; then the flatty fibrous capsule was pulled out with forceps until the tension held the kidney just above the twelfth rib, but allowed it to move slightly with respiration. The surplus capsule was cut, and the ends sutured to the fascial lining of the muscles about the opening with silk, and the muscles were closed with catgut. After this operation the kidney was usually in its normal position, and also possessed normal mobility.

Results Obtained by Fixation of the Kidney by Present Methods.—Dr. Alexander B. Johnson read a paper with this title. He stated that the object to be obtained was the replacement of the kidney without interference with the functions of the ureter or disturbance of the colon. The methods adopted by different surgeons to obtain this result were then detailed. He considered Piddell's method of operating a good one, and preferred catgut for the sutures.

Dr. Joseph A. Blake considered that the failure to fix the kidney under the diaphragm arose from its rotating on its upper pole, and thus coming to lie horizontally. In suturing, the stitches might be passed through either the fatty or the fibrous capsule, as their support was useful only until granulations formed. Catgut was the best material.

Dr. John F. Erdmann discussed the frequency of appendicitis occurring with displaced kidney. Fixing the kidney did not relieve the symptoms in these cases or when splanchnoptosis was present. As the rapid healing of the kidney wound was the important point, the matter of suture was secondary; in fact, if the patient could be kept quiet enough suture might be dispensed with. Kangaroo tendon was the material he used.

Dr. A. H. Goelet said that the danger in movable kidney was not its mobility, but its too low displacement. Unsuccessful operations were often due to lack of proper care before operation and imperfect freeing of the capsule, during operation, from the adhesions with the intestines. He condemned catgut as too liable to stretch. His own preference was for silk.

Dr. Edward Wallace Lee advocated splitting the capsule and rolling it back on each side until a scroll was formed, and then suturing through this thick roll, thus securing a better hold for the stitches. When catgut was treated with silver salts, according to the Credé method, it became strong and non-stretchable.

Dr. Wylie, in closing the discussion, repeated his conviction that, in replacing a kidney, it should be suspended and not fixed; but added, that he had come to operate less and less, as he thought more good was accomplished by attending to the complicating abdominal and pelvic troubles, and to the general health.

The Coroner's Office.—The special committee appointed to consider the advisability of abolishing the Coroner's office consisted of Drs. Stephen Smith, Harry R. Purdy, and E. Eliot Harris. The committee, after long deliberation, brought in a carefully-prepared report recommending such legislation as would lead to the abolition of the office of Coroner and the transfer of the duties of that office as follows: (1) The duties of investigating the causes of death in all cases now coming under the jurisdiction of the Coroner to be transferred to the Health Department, and the authorization of the latter to organize and equip a bureau for that purpose and appoint the necessary officers; (2) the transfer of the legal duties of the Coroner to the District Attorney's office, and of the judicial duties of the inquest to the Magistrate's Court; and (3) the transfer of duties, other than those pertaining to the inquiry into the cause of death and inquest, to the Chamberlain.

Street-car Service.—At the suggestion of the Committee on Public Health, the Association endorsed the recommendations made by the Merchants' Association to the State Board of Railroad Commissioners.

Infantile Diabetes Mellitus.—Howard E. Lomax reports several cases of this affection. Its etiology, he says, is more obscure than in the adult form. Heredity seems to play the first rôle, although the heredity is seldom direct; it is the predisposition to the disease that is inherited. It is said that diabetic children belong to families in which phthisical, uric acid, or neuropathic affections prevail; dentition, diet, rapid growth, unhygienic surroundings, excesses of various kinds, injuries (especially of the head and vertebral column), and pre-existing disease have all received their share of blame. Gastric catarrh is the most notable pre-existing disease. As lesions of the pancreas are liable to give rise to diabetes in the adult, it is reasonable to suppose that some of these lesions can also produce the same disease in children. The treatment of infantile diabetes embraces dietetic, hygienic, and medicinal means. The latter have little or no effect. Hygienic remedies are of great value, as they stimulate oxidation. As to diet, carbohydrates should be reduced to a minimum. Most authorities allow milk in moderation. No recoveries from infantile diabetes mellitus have been reported.—*Albany Medical Annals.*

Book Reviews.

Twentieth Century Practice. An International Encyclopedia of Modern Medical Science by Leading Authorities of Europe and America. Edited by Thomas L. Stedman, M.D., New York City. In Twenty-one Volumes. Volume XXI. Supplement. New York: William Wood & Co., 1903.

Sufficient progress has been made in the medical world to justify the publication of a supplementary volume to the Twentieth Century Practice, and the editor has made a wise selection of subjects, which are ably presented by various authors in the work before us. Dr. Beck writes on the Röntgen Ray in Medicine, giving the technique, the errors liable to occur, and the therapeutic application, of this new power in medicine. Mr. Roger Williams reviews the subject of the theories of the cause of cancer and gives a very just résumé of the work that has been done up to the present time. Bacillary dysentery is fully described by the discoverer of the causative germ, Dr. Shiga of Japan, and he presents statistics which seem to prove the efficacy of the serum treatment, the confirmation of which would prove a boon to those countries in which the disease is common. American physicians will take special pleasure in reading Sternberg's account of the discovery of the transmitting agency of yellow fever. The wonderful practical results starting from these investigations are a natural source of national pride. The subject is fully treated in the text, and a few charts and illustrations add to the interest. Higley brings the chapter on the blood fully up to date and presents it in a concise form. Among many other diseases we note short chapters on the Nose, Pharynx, and Larynx, on the Skin, on the Lungs, Œsophagus, Stomach, Liver, Aorta, Brain, Spinal Cord, Infectious Diseases, Diabetes, Rheumatism, and Gout. Taken in conjunction with the preceding twenty volumes, the present one makes an exceptionally complete and satisfactory encyclopedia of medicine thoroughly up to date, written by those recognized as authorities and ably edited.

Tratado Teórico-Práctico de las Enfermedades de los Niños. Por el Doctor Francisco Criado y Aguilar, Catedrático de Enfermedades de la Infancia con su Clínica en la Facultad de Medicina de la Universitad Central. Madrid: Imprenta del Asilo de Huérfanos del S. C. de Jesús, 1902.

In this excellent treatise on the diseases of children, by one of the foremost pediatrists of Spain, the reader will find much that is of interest and value as well as some points that are novel. Practice necessarily varies in the different countries, despite the ready means of communication and the mutual interchange of views at international congresses and through the medium of the medical journals, and it is, therefore, of great service to study the literature of other countries. One who would study the diagnostic and therapeutic methods characteristic of pediatrics in Spain and compare these methods with those most familiar to him could not do better than to study them in this work by Criado y Aguilar.

In spite of the limits which the author has set to his subject, treating only of the diseases peculiar to childhood or of the general maladies which differ markedly in symptoms and course according as they attack the young or those in adult life, the book is one of over eleven hundred pages. The work is divided into two parts—Paidología and Paidopatía. The first embraces the hygiene of infancy and childhood, including the subjects of alimentation, clothing, exercise, intellectual labor, and hydrotherapy. In the second part the diseases of children are systematically studied, beginning with the special pathology of the new-born and then proceeding to vices of conformation, eruptive fevers, diseases of special organs or systems, dermatoses, infantile syphilis, diseases of growth, and maladies dependent upon disorders of nutrition.

The treatise, being in Spanish, will unfortunately be a sealed book to many, if not most of those who might otherwise profit by it in this country, but it will doubtless be appreciated by the physicians of Latin America, and we cannot but congratulate them upon the opportunity offered to the in the publication of this exceptionally valuable work.

The Practical Medicine Series of Year Books, comprising Ten Volumes on the Year's Progress in Medicine and Surgery. Under the Editorial charge of G. P. Head, M.D., Professor of Laryngology and Rhinology, Chicago Post-graduate Medical School. Vol. II. General Surgery. Edited by John B. Murphy, M.D., Professor of Surgery, Northwestern University Medical School, November, 1902. Chicago: The Year Book Publishers.

This volume is the second of a series which promises to contain many features of usefulness for the general practitioner, for whom it is chiefly intended. Much the same plan is followed as is seen in larger textbooks, by which the subject under discussion is divided into regions, each of which receives its share of attention. By issuing ten volumes on separate subjects, it is possible to go much more into detail than in the ordinary year book, and the views of the various authors are in consequence much more accurately given to the reader. This volume contains many epitomized extracts on all sorts of surgical subjects which have been under discussion during the past year, and its perusal will give one a good idea of recent surgical literature. The size of the volume is convenient, and the extracts have been carefully edited.

Flowers of Song from Many Lands. By Frederic Rowland Marvin. Troy, N. Y.: Porfracts Book Company, 1902.

This is a charming collection of short poems and isolated fragments of verse taken from many languages and translated into English. The translation is into smooth and poetical language, giving to the fragments an appearance of originality not often seen in translations, especially metrical translations. The selection of the poems also has been made with great discrimination and taste, some of them being exquisite little gems, inaccessible to the average reader. The edition before us is a limited one, but we hope the publishers will issue the book again in popular form, so that to all lovers of the beautiful in verse may be given the opportunity to possess themselves of this excellent collection.

Lessons and Laboratory Exercises in Bacteriology, an Outline of Technical Methods Introductory to the Systematic Study and Identification of Bacteria, Arranged for the Use of Students. By Allen J. Smith, M.D., Professor of Pathology in the University of Texas, Galveston. Philadelphia: P. Blakiston's Son & Co., 1902.

This book is intended as a laboratory guide for the student in bacteriology, and is an amplification or outgrowth of the schema of exercises carried out by the author's class under the guidance of an assistant. The book is printed only on one side, the odd pages being left blank for notes on the outcome of the various experiments and on special methods of technique. The work is well planned to carry the student through a complete course of instruction from the beginnings in sterilization methods to the technique of the various cultures, the isolation of bacteria and their classification and identification.

Progressive Medicine. A Quarterly Digest of the Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics, and Materia Medica in the Jefferson Medical College of Philadelphia; Physician to the Jefferson Medical College Hospital, etc., assisted by H. R. M. Landis, M.D. Volume IV. December, 1902. Diseases of the Digestive Tract and Allied Organs, Liver, Pancreas, and Peritoneum; Anæsthetics, Fractures, Dislocations, Amputations, Surgery of the Extremities, and Orthopedics; Genitourinary Diseases, Diseases of the Kidney, Physiology, Hygiene, Practical Therapeutic Referendum.

In this excellent volume the different contributors have, as in former issues, carefully noted the steps of value that have been taken all over the world during the last three months of the past year. The title is a good indication of the ground covered, and each of the subjects therein mentioned has been treated with all due consideration. The style throughout is terse and notes clearly the points of value that have appeared in each branch, and the references are extremely complete. The sections on Surgery, Diseases of the Kidneys, Hygiene and Therapeutics are worthy of special mention. In the latter there is a chapter on Röntgen Therapeutics, which should be particularly useful to the practitioner who has not time to search all of the literature of the subject.

The volume will prove of the utmost value to the general practitioner and to the specialist, who will be able, with the minimum of time and labor, to locate all of the important literature on any of the subjects treated, or to read an exceedingly clear and concise digest thereof.

Estudio de un Sistema de Alcantarillado para Málaga. Por el Tercer Teniente de Alcalde, Don Ramón Martín Gil. Málaga: Viuda y Hijos de J. Giral, 1902.

Although this is an essay on a system of sewerage recommended for adoption by the city of Malaga, and as such of local interest chiefly, yet the general considerations and the discussion of the advantages of the system advocated will be of interest to public hygienists in general. The author is Dr. R. Martín Gil, the well-known gynecologist of Malaga.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending February 28, 1903:

	Cases.	Deaths.
Measles	226	10
Diphtheria and croup	341	42
Scarlet fever	288	14
Smallpox	4	..
Varicella	137	..
Tuberculosis	298	187
Typhoid fever	34	12
Cerebrospinal meningitis	..	..

Instructions for Venereal Patients.—The following card is given to all patients suffering from syphilis in Dr. Follen Cabot's clinic: Syphilis is a constitutional disease. It is in the blood. Local remedies and taking medicine for a few months will not cure you. You must be treated for three years. The effects of this disease are far-reaching, and if treatment is neglected, much trouble and suffering will be caused, not only to yourself but to others. The following rules must be observed during the first year: Sexual intercourse must not be indulged in. Alcohol in all forms should be avoided, as it always aggravates the disease. Do not smoke or chew tobacco. Sleep alone. Under no circumstances should anyone be allowed to use your toilet articles, as brushes, towels, combs, razors, shaving brushes, etc. No article that has been in your mouth should be used by others, as tooth brushes, tooth picks, pencils, pipes, cigars, cigarettes, forks, spoons, drinking cups, etc. You must not kiss anyone, especially children. Brush your teeth night and morning, and keep your mouth clean. If you have bad teeth, have them attended to by a dentist, and be sure to tell him that you have syphilis, so that he may take necessary precautions to avoid the possibility of infecting others. Acids in food and drink should be limited." A similar and appropriate card is given to those having gonorrhœa.—*Modern Medicine.*

Saline Diuresis.—The absorption from the renal tubules in the rabbit when the outflow is obstructed is differential, the water and chlorides returning to the blood much more readily than the sulphates, phosphates, urea, and pigment. The presence of these last in the glomerular secretion must, therefore, tend to retard the absorption of water by opposing osmotic resistance to the absorbing force. When, as after their intravenous injections, they are present in large amounts, the urine is increased more than when such permeating bodies as the chlorides are in excess. If the absorption in the tubules under normal circumstances is similarly differential, as appears probable, this is sufficient explanation of the variation in the diuretic action of different salts. The saline diuresis appears to be not to stimulation of excretory cells in he kidney primarily, but to the changes in the circulation of the kidney; for when these are excluded, the injection of salt solutions causes little or no change in the urine, and on the other hand, an increase in the volume of the blood without change in its constituents appears sufficient to induce diuresis.—Cushing in *Journal of Physiology.*

Vitality and Low Temperatures.—The remarkable results of the experiments of Professor Macfayden and others on the effects of low temperature upon organic life render it highly desirable to ascertain how long vitality can be retained under such conditions. With liquid air now so available it becomes possible to extend the inquiry for an indefinite number of years, for a generation if necessary. The fact that bacterial organisms, after having been subjected for six months to temperatures far below those at which vital activities are supposed to be possible, and that they have retained their vitality practically unimpaired, profoundly modifies the conceptions hitherto attached to the word "life." If it can be shown that vitality can survive for a protracted period under such circumstances, the conclusion that life is a molecular function seems inevitable. If such an experimental result were obtained, it would greatly strengthen Lord Kelvin's speculation that the origin of life on earth may have been extra-terrestrial. Lord Kelvin, it will be remembered, suggested that the first germs of life on our planet might have reached it in the body of a meteorite from space.—*New York Sun.*

The Foreign Quarter of New York.—Few people realize what a large foreign population there is in New York. The following extract from an article on New York City, from *Pearson's*, gives a comprehensive idea of the foreign quarters: "As to the international character of the population of New York, it is one of the largest German cities in the world. The native Germans number 322,343, including people of German parentage, it is said to be the third largest German city. The Irish number 275,102; the Russians and Poles, from which the Jewish population of the Ghetto mainly is drawn, 188,000. There are about 100,000 people in New York who cannot speak English; many of these belong to the large Italian population. Last year 136,455 Italian immigrants landed at the Port of New York, the total immigration through this port for the year ending July 1 being 493,380, the largest on record. The foreign population of New York, with its churches, clubs, societies, and other institutions, give New York such a cosmopolitan character that you can worship in almost any language and swear in as many more and be understood.—*Scientific American.*

Statistics of the Medical Profession in Germany.—Dr. Wehmer's Medical Directory states that there are now 28,127 medical men in Germany, as compared with 27,039 in the previous year, 26,479 in 1900, 26,049 in 1899, 25,178 in 1898, and 24,303 in 1897. The increase of 1,088 in the number of medical men from the year 1901 to the year 1902, is an increase of 4 per cent. and is greater than in any previous year. During the past five years the numerical increase of the medical profession was 3,734, or 15.2 per cent., while the increase of the general population was 9.3 per cent. As regards distribution throughout the various States it is found that 17,126 medical men reside in Prussia, 2,790 in Bavaria, 2,148 in Saxony, 1,147 in Baden, 937 in Würtemberg, 814 in Alsace-Lorraine, and the remainder in the smaller States of the empire. There are 2,366 medical men in Berlin, 583 in Munich, 573 in Hamburg, 548 in Breslau, 433 in Dresden, 431 in Leipsic, 344 in Cologne, 354 in Charlottenberg, 338 in Frankfort, and 304 in Königsberg.—*Lancet.*

The Dangers of Acetylene.—It may not generally be known how much danger may exist in the use of acetylene for even toy purposes, owing, no doubt, to the want of a proper understanding of its manipulation and use. A lamentable accident occurred recently to a youth, aged sixteen years, who essayed to light the lamp of his magic lantern with acetylene gas. Having provided some calcium carbide, he sought to use it in accordance with instructions gathered from sundry papers and journals. In the course of these efforts there was a loud explosion and the boy was burnt so much that he died subsequently from the injuries received—which shows once more that a little learning is a dangerous thing, more especially in dealing with substances of such potency as those used by this unfortunate youth.—*Lancet.*

Transmission of Lepra.—A fact of interest in the determination of the transmission of lepra, is that although there is no isolation of lepers in Egypt, there are very few of them there. This, taken in connection with the warmth and dryness of the climate, suggests that dampness and cold may have an influence upon transmission.

SOME OBSERVATIONS ON VULVOVAGINITIS IN CHILDREN (WITH SPECIAL REFERENCE TO THE GONORRHŒAL FORM); ITS TREATMENT AND POSSIBLE SEQUELÆ.

By SAMUEL WYLLIS BANDLER, M.D.,
NEW YORK.
INSTRUCTOR IN GYNECOLOGY, POST-GRADUATE MEDICAL SCHOOL

Gonorrhœal Vulvovaginitis.—A purulent vulvovaginitis is not very rare in children. It is due, in the vast majority of cases, to the gonococcus. It is likewise due to a small coccus, also found intracellular, but which certainly is not the gonococcus.*

On inspecting a specific case there will be seen a profuse discharge, which accumulation is greatest in the upper portion of the vulva and about the clitoris, in which area the discharge is also thicker and drier. The vulva itself, external to the large labia, is red, inflamed, and œdematous, pitting on pressure. The main irritation is in the immediate circumference of the hymen, of the lining of the smaller labia and of the perineum or fourchette. The sulci between the smaller labia and the future labia majora are most affected, being of a very dark red color, often with a deep bluish tinge. The vagina is less frequently affected to so great an extent. If treatment be devoted mainly to the vulva or to the vagina, improvement is relatively slow. The opinion of many that the specific form is always a vulvitis and not a vaginitis is decidedly wrong. While this is true in some cases, it is by no means the rule, as I have several times disproved by first washing the vulva and outer end of the vagina thoroughly, and then observing the expression of pus from the vagina when the child cried or resisted efforts at treatment. Further, on the use of the small speculum the red and inflamed character of the vaginal lining and the *erosion of the tiny cervical os* and the presence of pus are very distinctly recognized.

A continued irritation of the tissues leads to some of the local anatomical lesions which occur in adults, of which I mention condylomata. Eight were present in one case and were found on the perineum, the large labia, and especially on the skin surrounding the clitoris, which in children is relatively large and thick. Condylomata may also be found in the neighborhood of the anus. In one case a purulent secretion was found exuding from the anus, and examination evidencing the presence of gonococci, the diagnosis of proctitis was made. In another case the lesions were of a more acute character, minute fissures being present and causing pain and passage of blood on defecation. The treatment for this condition is irrigation with a 2-per-cent.-protargol solution and the introduction of a 2-per-cent.-protargol suppository.

The main evident lesion in gonorrhœal vulvovaginitis is the affection of the vulva immediately about the hymen, the inner labia, and the perineum. Frequently, the cutaneous covering of and about the external genitalia is likewise affected. No matter how thoroughly the former of these lesions is treated, unless the entire skin periphery be likewise treated, secretion will continue. The red, irritated character of the skin covering of the vulva is not due to irritation by the secretion alone, but to an actual invasion by the gonococci of the superficial layers of the epidermis. During the acute inflammatory stage the section surrounding the clitoris is least affected.

For the vulvitis, I paint the areas thoroughly with a 10-per-cent.-silver solution, which, strange to say, causes relatively little pain. All the areas up to the hymen must be thoroughly painted, and the sulci between the inner labia and the outer, the perineum, and the outer surface of the hymen, must be thoroughly touched. The child should, once or twice a day, be seated for fifteen minutes in a very warm sitz-bath, for the purpose of removing, as far as possible, the superficial desquamating layers. During the entire period, between treatments and best applied immediately after the bath, a 2-per-cent.-protargol ointment, freshly made, is the ideal external medicament.

For irrigating the vagina I use a thick rubber tube with a lumen one-third of an inch in diameter. Into this I insert a urethral rubber catheter, leaving one inch extending beyond the end of the rubber tube. The catheter is then inserted into the vagina for the purpose of irrigation. The thick rubber tube which covers the catheter, if pressed closely against the hymen and the outer end of the vagina, prevents the outflow of fluid, and thoroughly distends the vagina with the irrigating medium. On gradually releasing pressure by the outer tube, the fluid makes its exit without squirting into the face of the attendant. If, then, the speculum be introduced, and the fluid be removed by thin swabs, a clear picture of the local lesions can be obtained, and the treatment to be mentioned can be applied.

Treatment.—At first these cases were treated by me, so far as the vagina is concerned, by irrigation with boracic solution and the installation, with a curved eye-dropper, of several tubes of 2-per-cent.-protargol. Another mode of treatment, more applicable in the later stages, is the injection with the eye-dropper of silver solution, followed by the installation of ichthyol solution. I now consider the best daily ambulatory treatment to be (1) irrigation by boracic solution; (2) injection of protargol solution into the speculum; (3) washing of the entire length of the vaginal canal with the aid of the speculum;

*Of eight cases of purulent vulvovaginitis seen within a period of three months two were of the latter form. The younger of the two cases was a child four months old, which had been operated on for mastoiditis. In the hospital it acquired its vulvitis; the mother stated that many other children were likewise affected. This form presents almost the same local lesions as the specific form, but the discharge is less green in color and less purulent. It is also healed more readily. In discussing gonorrhœa in children, we are first concerned with the form of onset, which is that of a purulent vulvovaginitis. (Diagnosis by the microscope.)

(4) after which I would advise the introduction of the protargol stick; (5) the subsequent use of strong silver solution if necessary.

Improvement is evidenced (1) by the character of the secretion, which gradually becomes paler and thinner and less in amount; (2) by the gradual disappearance of the red inflamed character of the acutest lesions and the resumption of normal color on the dermal covering of the vulva; and (3) by the healing of the vaginal and cervical erosions.

Gynecological examination in the adult involves the use of the bivalve speculum. With this we obtain a direct view of the cervix and of a portion of the fornices. We judge readily the lesions on the portio, the character of the external os, and of the secretion, mucoid or otherwise, extending from the cervix. Even under favorable circumstances, however, the light gives an indistinct picture, and no exact opinion of color or real size of the cervix can be gained. The action of the bivalve speculum exerts a tension on the anterior reflection of the vaginal wall extending upon the cervix. For this reason, especially if there be any tears, the cervix seems larger than it really is, and often appears of a very great size. If an idea as to the character of the vaginal wall is to be gained, light conditions again give an indistinct picture, and it is impossible, without annoyance to the patient, to turn the speculum so as to disclose all points in its circumference. Further, the mucous membrane lies in folds between the opening of the two valves, if the speculum be turned, and on approaching the external opening of the vagina the discomfort is pronounced. These objections are not overcome by the use of the Sims' speculum, or of any other form, with one exception.

In using the Ferguson speculum we are able to closely examine every bit of the vaginal wall up to and including the cervix. The light conditions are most admirable and give the only distinct picture of the local conditions of anæmia, congestion, and inflammation. Localized and diffused areas of congestion, and minute lesions of various forms, can be distinctly seen. The cervix, on complete introduction of the speculum, is distinctly outlined, and an opinion as to its real size is here of value. The treatment of the portio and of the cervix itself can be easily carried out with the use of this instrument.

Quite equal to its diagnostic value is its aid in treatment. When treatment of the fornix is desired, the application on a swab of carbolic acid or iodine, or the use of a cautery, may be carried out without fear of injury by contact with other tissues. The area desired can be extended at will, for the fluids introduced affect only the points exposed beyond the end of the speculum. A most important feature is the ability to apply fluids of any sort and in large amounts. These bathe, for any desired length of time, the entire length of the vaginal canal. By withdrawing the speculum up to the external opening of the urethra, the fluid is brought in contact with the entire lumen of the vaginal canal, for any desired length of time. On again introducing the speculum and depressing the outer end, the fluid flows out without coming in contact with the perineum, rectum, or external genitalia, and the little residue may be removed with absorbent cotton. Through this speculum the vagina may be painted with any solution or thoroughly coated with any powder. The introduction of tampons or gauze is easily carried out in an even manner, while through the ordinary speculum packing of the vagina results in a more or less irregular overdilatation of certain areas. When a vagina is thoroughly packed with long strips of gauze through a Ferguson speculum, it is easily held in place without exerting much pressure upon the rectum. The introduction of a tampon just filling out the lumen is of valuable aid in lifting and supporting the uterus and relieving it from congestion and œdema.

Owing to the admirably reflected light, I have devised a small Ferguson speculum fitted for the same purpose in children. In them the vagina is of great length, of a curved course. It is remarkable how distinctly through the small speculum the color and character of the vaginal lining may be seen, and the tiny cervix, with its tiny opening, can be distinctly put in view. In this way, too, quite naturally, applications of fluids on a swab may be carried out in the same manner as in adults, and a vaginal bath with any desired liquid may be carried out with the greatest of ease, limiting its action completely and preventing any undesired irritation of the vulvæ, perineum, vestibule, or urethra.

The hymen of the child is very thin and very elastic, quite as elastic as the foreskin of the male. In the numerous instances in which I have used a curved eye-dropper or the vaginal speculum, I have never found difficulty, even in the smallest children, in entering the vagina, nor have I ever torn any tissues or produced a bleeding. Care is necessary in the first examination to determine if any attempted violence has produced local lesions beyond those of the infection—*a factor which, as a rule, explains the etiology*. It is by no means easy to determine this fact. As mentioned, an attempt may have been made without injury or penetration, yet producing infection. A method which has served me, however, is the irrigation of the hymen with a large stream of water, under mild pressure. The normal hymen is then brought into undulation, and its margin is distinctly outlined. Any tears or lesions will be evident as irregularities or interruptions in the normal unbroken edge of this structure.

The cure of a vulvites of specific character is not so very difficult. If, however, we are dealing with an invasion of the vagina and *cervix*, an absolute essential to a certain cure is complete rest in bed. Other essentials are (1) frequent irrigation; (2) frequent washing of the affected areas with protargol and (3) in the subacute stages, with silver nitrate.

The results in my cases were good if the cervix was free. A cure results within six to twelve weeks by almost daily treatment. If the cervix be affected, renewed virulent attacks may occur after apparent cure, though it is impossible to deny that in some cases a repetition of the original etiological factor may have occurred. Ambulatory treatment is certainly unsatisfactory. *These should be hospital cases.*

However, in the words of Bumm, "*all gonorrhœas heal, if they do heal, finally through the natural reaction of the infected tissue. Without this help the complete elimination of the gonococcus is impossible. Most unpromising, therefore, are the chronic cases in which the tissue is accustomed to the gonococcus and the mucosa epithelium, through long irritation, has undergone metaplastic change to stratified squamous epithelium, and only a slight secretion is found, consisting mainly of squamous epithelium. The cocci diminish or disappear under treatment, but on cessation of the latter reappear. Therefore, constitutional treatment is often necessary.*"

The Sequelæ of Vulvovaginitis.—The importance of this question is due to the fact that (1) *all the lesions of the adult may be reproduced in the child*, and (2) a permanent injury to be avoided is one or other of the forms of *atresia of the hymen or of the vagina*. One of the purposes in using the dropper or the speculum was to avoid this

danger, for there is a beginning or well-advanced adhesion of the hymen or lower portion of the vaginal tract.

For many years Bumm and Wertheim have been the leaders in a controversy concerning the relation of the gonococcus to the tissue on which it is implanted. Bumm assumes that in the vast majority of instances the gonococcus is a *parasite*, growing on the superficial layers of the various mucosæ. Wertheim states that the gonococci may enter the subepithelial connective tissue in every case. It is well, therefore, to review the microscopical characteristics which form the basis for the latter opinion.

Although Bumm denies that in the vagina of adults the gonococci enter the subepithelial connective tissue, Mandl found in sections through the wall in a case of gonorrhœal vaginitis (1) the surface epithelium gone; (2) all the epithelium gone in spots; (3) gonococci entering into the epithelium in rows and in bands; (4) the gonococci very deep in the tissue in spots and *extending beyond the epithelial limit*. Though the gonococci were generally in the superficial connective tissue, *in certain areas they were deeply imbedded*. The granular character of the vagina observed in two cases of gonorrhœal vulvovaginitis in children makes it evident that the pathology of the lesions may be the same as in this severe case in an adult.

In a case of gonorrhœal salpingitis treated for three years (*continuous irritation*) a laparotomy by Wertheim showed the presence of an acute gonorrhœal peritonitis. The serosa of the pelvis, of the uterus, and of the adnexa was highly injected and covered with a layer of cloudy pus-like fluid, which was also present in the sac of Douglas. This exudate contained pus and intracellular gonococci. The posterior surface of the uterus and of the ligamentum latum of the left side was covered with thin white membranes, which could be lifted off in small pieces. The serosa thus uncovered was rough, dark red, and looked like eroded tissue. These membranes proved to be composed of pus-cells, fibrin, and intracellular gonococci. Out of the abdominal end of the right tube came a white creamy pus containing gonococci. They were also found in the serosa and in the tubal tissue, proving that infection of the peritoneum may occur through the wall of the tube, though in this case, as in the majority of instances, it occurred through the abdominal end of the tube.

Frequent as is the occurrence of a gonorrhœal urethritis in the female, extension of the inflammation to the bladder was referred for a long time to a complicating cystitis due to other bacteria, or to an involvement by the gonococci of the neck of the bladder alone. In recent years numerous instances of a pure gonorrhœal cystitis make its entity positive, but in the early days Barlow was one of the first to find, in two cases of cystitis, only gonococci in the urine. The cystoscope showed a diffuse inflammation of the entire bladder mucosa. Krogius, in two cases of purulent cystitis, found numerous gonococci in the epithelial cells in the urine. Wertheim, Bierhoff, and others have verified this condition many times.

In a nine-year-old child with purulent cystitis, Wertheim found only gonococci. In narcosis a piece of the bladder-mucosa was removed with the aid of the cystoscope. Gonococci were obtained in cultures made from the excised specimen. The microscopic sections of the specimen showed (1) gonococci between the epithelial cells; (2) gonococci *extending in rows into the subepithelial connective tissue* and lying almost entirely extracellular; (3) the surface of the mucosa covered with fibrin layers; (4) gonococci *in the blood vessels*. When found in the blood vessels the gonococci were not always of typical form, but were rather involution forms and groups looking like masses of granules.

In further proof that the gonococci may enter the subepithelial connective tissue in every case, Wertheim has shown that they are found, for instance, in the subendothelial connective tissue of the peritoneum, in the bladder wall, in the wall of the vagina. They have been found in the connective tissue of the synovia in gonorrhœal arthritis, in the tube wall, in œdema of the foreskin of the penis, in myocarditis gonorrhoica, etc. As a general rule, the gonococcus causes no pus in connective tissues, but can do so, as in ovarian abscess, periurethral and perichondrial abscess, in abscess of the uterus, in abscess of the cervical glands, abscess on the dorsum of the metacarpus, about the knee-joint, etc. As a factor in mixed infection, the gonococcus has been found in cystitis, arthritis, bartholinitis, some cases of adnexitis, etc.

On the other hand, in further support of his contention, Bumm states that in a chronic cervical gonorrhœa *the cocci are limited to isolated small areas of mucosa* in which the cocci are situated in metaplastic squamous epithelium. The epithelium of the glands he believes to be generally immune, holding also to the belief that, while the duct may be invaded by gonoccoci, the gland of Bartholin is not so affected. In the uterus he finds the mucosa affected, *as a rule, in localized areas, and only superficially*.

It is undoubtedly the experience of men who have had large numbers of cases under their close observation that neither the contention of Bumm, nor that of Wertheim, form an absolute rule. There is no doubt that *different individuals react differently to the invasion of the gonoccocus*, and the amount of discharge, the acuteness of the inflammation, *the depth or extent of the invasion*, the duration of the affection, and *the results of treatment* in the various forms of this inflammation, differ greatly. *The care the individual can take of himself has an important bearing on the various features of this disease*. For instance, the peritoneum not being an epithelial tissue, is supposedly resistant to the invasion of the gonococci. An introduction of gonococci into the peritoneum often causes no reaction in animals, but the same is true of streptococci and staphylococci. A predisposition is necessary, and this consists either in *a mechanical or chemical injury* to the peritoneum. Therefore, on introducing, in animal experimentation, together with the gonococci a nutrient medium which is not easily absorbable (such as hard serum-agar covered with a culture of gonococci) an inflammation is produced. In the human being, as may be seen from the case of Wertheim, it is not the simple exit of gonococci through the outer opening of the tube so much as it is the constant or repeated outflow of gonorrhœal pus into the peritoneum (*constant irritation*) which produces the inflammation (Wertheim.)

On epithelial media the course is a different one. The invasion of the epithelium is the first step. The gonococci pass between the epithelial cells down to the connective tissue. There is a decided exudation of leucocytes from an extensive periphery into the connective tissue and through the epithelium. There is then *a change of the epithelium to the squamous form* and a growth of the cocci in the superficial epithelial layers. Here, too, there is a difference dependent on the character of the epithelium. The softer and thinner the epithelium, the easier does this coccus invade the tissues. It increases very rapidly, and the number of bacteria trans-

planted has nothing to do with the period or virulence of the inflammation. The tender covering of the vulva and vagina in children is easily affected. In adults the infection of the urethra frequently calls attention to the condition, because of the annoyance on urination. The infection of the vagina alone may result in a large amount of secretion, but often the external genitalia are not much affected, and no annoyance is experienced for weeks or months. In adults the urethra and cervix are often affected, and the vagina but slightly, while the vaginal epithelium of children, not being so hard and dry, is readily affected. Secretion from the cervix in the adult may often be free of gonococci, yet their presence after menstruation and post-partum is often noted. Thus congestions of a normal character, and doubly so congestions of a pathological character, have an important bearing on the continuation and extension of the inflammation.

Invasion of the anus and rectum likewise occur more readily in the tender epithelium of the child than in that of the adult, but here, too, it is the continued discharge with its consequent continued irritation which is an important factor.

When growing on a mucous membrane, where, through continued secretion, new medium is constantly produced, the gonococcus thrives better than when encapsulated in an abscess, in which case the coccus may die affected by its own toxins, or by the action of other bacteria. As early as six weeks after an acute gonorrhœal infection, gonoccoci were absent in a pelvic abscess which had been opened. Just as in a culture medium colonies of gonococci die within one or two weeks if not transplanted, so the gonococcus in a chronic case is weakened in its virulence to the affected human being. Being fed, however, by new secretion, it does not die, but becomes less virulent, adapts itself to the bearer, and a chronic or subacute inflammation results. In the adult we have a special factor. Just as transplantation to fresh media prolongs the life of colonies of gonococci, so does the coccus when moved from a chronically affected region to a new area (the irritation of coitus, of labor, of exertion, treatment) and especially *when transplanted to a new individual* produce an acute inflammation. In the latter instance, *when retransplanted to the first bearer*, it causes again an acute inflammation on the base of the chronic form (Wertheim).

The typical characteristics of gonorrhœa are (1) an acute beginning; (2) a chronic course; (3) resistance to treatment; (4) virulence in new areas or new media for a very long time; (5) probable extension in continuity; (6) possible constitutional involvement.

The pathology of various lesions shows the possibilities to be (1) superficial involvement of the mucosæ; (2) *deep involvement extending into subepithelial connective tissues;* (3) abscesses; (4) metastases; (5) constitutional involvement; and (6) which is very important, *the early formation of adhesions.*

Though all the lesions in the adult may be reproduced in children, yet the absence of menstruation, of labor, of pathological congestions, of intercourse, together with the minute development of the uterus prevent, as a rule, the involvement of the urethra, the uterus, tubes and peritoneum, though these involvements in children are by no means unknown. Constitutional involvement may occur from any point. Important pathological changes and injuries of a permanent character may be located, in children, primarily in the *hymen, vagina, and cervix.*

An atresia may involve the hymen or the vagina. This condition has been generally viewed as congenital. The investigation of Neugebaur, however, shows that among the reported cases of stenosis or atresia 251 are congenital and 469 *are acquired.* The investigations of Nagel and of Veit show that an *atresia vaginæ with a normal uterine canal is usually acquired,* except those cases occurring through epithelial union in utero, which constitute the *accidental intrauterine form,* since they are not due to failures of development. If the uterus be normal, no proofs can be found to show that the atresia exists since birth, but if a mal-development of the vagina and an *absence* of its lumen is to be diagnosed, the uterus must be also mal-developed and two-horned. According to Nagel, the lumen of the vagina is formed in the embyro through grouped masses of epithelium which separate the vaginal walls in their entire length and then degenerate, leaving a lumen in the resulting canal. For this reason, epithelia are found in the vagina of the newly-born and for a varying period afterward. The epithelial detritus in the vagina of the child may be mixed with mucus, which is small in amount, and, therefore, in the newly born a conglutination of the vagina or the hymen is possible. Henoch found a conglutination of the labia minora in later stages by no means a rarity. Piering divided the acquired stenoses and atresiæ into (1) traumatic; (2) inflammatory; (3) chemical, and (4) thermal. The first two causes are important.

Any irritation, as enuresis, may cause excoriation with a conglutination of the hymen. Such conditions often obtain in the newly born and are not recognized. In infectious diseases there is often a colpitis adhæsiva without symptoms. A conglutination may occur through the excessive size of the hymen and the constant rubbing. The hymen in the newly born is not a diaphragm, but is a very thin lip-like circular prominence extending out of the vagina. The posterior lip is the more prominent. Sometimes the hymen is polyp-like or tongue-like, and so called linguliformis. It resembles most the anus of the hen (Nagel.) Sometimes it is situated further up in the vagina, and, therefore, if the vestibule is deep the vagina is short. If there be no hymen we are dealing with the sinus urogenitalis. The hymen in the newly born is often so large that it is mistaken for the labia minora. The vagina of the child is quite long, generally at least two inches or more.

Weak and anæmic children are more disposed to milder forms of vulvovaginitis than other children. The presence of milder forms of vulvovaginitis is often overlooked, while the failure of treatment in other cases is likewise a responsible factor in producing future annoyances. Milder forms of vulvovaginitis in children follow the course observed in adults. In the latter the source of irritation is to be located in the bladder, the vagina, or the rectum. The cases in which the rectum is mentioned as a causal influence are noted simply from the standpoint of etiology, for it is certain that after constipation, especially on the use of enemata, or after diarrhœa, the means of infecting certain areas of the genital tract are present. The element of personal cleanliness, or rather the lack of it, plays a part in infecting the bladder, and especially the vagina, and a bacterial infection is thus the basis which leads to pruritus vulvæ, irritable bladder, leucorrhœa, and vulvovaginitis. Irritable bladder is due then to a local pathological condition, and the urine and its contained bacteria must be credited with the power to produce external local irritations. The vagina of the newly born is sterile for only two to three hours, after which period bacteria are present. The numerous forms present in

leucorrhœal vaginal secretions of the adult or younger girls, are evident to any one who takes the trouble to examine a specimen under the microscope. The bacteria present in the normal vaginal secretion are those described by Döderlein, and are responsible for the acid reaction of the normal vaginal secretion. In addition there are found in numerous cases various forms of streptococci, staphylococci, bacterium coli, yeasts, bacilli, etc. In examining a leucorrhœal secretion we find three major forms: (1) one consisting mainly of leucocytes; (2) a form containing mainly vaginal epithelia, and (3) a form composed of both of these elements. As the normal vaginal secretion consists of epithelia alone, it would be strange to consider the second form, even though profuse, pathological, were it not for the presence of numerous bacteria. They may be found in such large numbers that they give the picture of a pure culture. They may be found between the epithelial cells or in them, and it is for this reason that a microscopical examination is necessary in the adult; for instance, to determine the form of treatment. The larger the number of epithelial cells and the more decided the invasion of the cells by the various forms of bacteria, the deeper in the vaginal mucosa has the involvement extended, and the greater the number of leucocytes the greater is the reaction. We must consider then even the milder forms of vulvovaginitis, or in some cases only vaginitis, to be bacterial in origin.

A *complete* conglutination of the hymen sometimes evidences a raphé, but the absence of scars or scar-rests in the hymen is no proof that an atresia is not acquired. It may break spontaneously. We may have also a conglutination hymenalis cribiformis. We may have atresia retrohymenalis, the anterior wall of the vagina uniting with the posterior surface of the hymen. A congenital conglutination of the hymen often breaks spontaneously, but, if acquired, is tenser because of the union of thicker hymen folds.

We know that various forms of atresia may occur in adults, even in multiparæ, as a result of a colpitis adhæsiva, or as a result of ulcerations accompanying fluor or leucorrhœa of gonorrhœal origin. It may also occur with fluor and leucorrhœa when not of gonorrhœal origin, if no menstruation or coitus take place, and that, too, without ulcerations and without annoying preliminary symptoms. In reviewing the history of girls affected with amenorrhœa, we know that this condition is due either to primary constitutional or a primary local cause, and it is the latter which is frequently overlooked. In children various degrees of *atresia*, *stenosis*, and *changes in the hymen* may occur as a sequence to gonorrhœa, to the milder forms of vulvovaginitis, or with and after the various infectious diseases (most frequently after typhoid fever and scarlatina).

The lesions produced by infectious diseases in children include vulvovaginitis. The first menstruation with acute infectious diseases, especially if amenorrhœa follows later, is really due to an affection of the vulva or vagina accompanied by a loss of epithelium, by bleeding, by the presence of ulcers, and easily by subsequent adhesions. The so-called menstruation præcox is often only such a vulvovaginitis. Scarlatina especially may cause thrombotic necrotic processes in the vagina.

Some of the results of atresia are more far-reaching than generally known. The occurrence of an hæmatocolpos with an atresia can be readily understood. The occurrence of an hæmatosalpinx, however, is one not so easy of comprehension. This condition, in a large proportion of cases, is of a dangerous character, for if it rupture into the peritoneal cavity *it produces a fatal peritonitis*. This results frequently when the atresia is removed, for a resulting contraction of the tube expresses the contents into the peritoneal cavity so that an abdominal operation is now considered the proper form of treatment. Veit asked: (1) How in some atresiæ of the vagina does an hæmatosalpinx originate? (2) Why, in rupture of a hæmatosalpinx due to atresiæ does an acute peritonitis result? (3) Is an atresia with a double genital canal but only a one-sided hæmatrometra, congenital or acquired? The theory of Nagel and Veit serves to explain the infectious character of such an hæmatosalpinx. The first and second questions are closely connected, for the contents of such a hæmatosalpinx are *the products of a bacterial inflammation*. Scarlatina, and especially gonorrhœa, produce local, often neglected affections which cause atresia and also a salpingitis with closure of the tubes. Typhoid fever, scarlatina, and measles may produce without symptoms an atresia, and the affection may extend through the cervix and uterus into the tubes, with closure of the latter. (Pincus.)

Mainzer finds that a closure of the abdominal end of the tube may occur through torsion and through perisalpingitic affections. He believes that bacteria may cause a hydrosalpinx or a pyosalpinx, but he does not believe that an hæmatosalpinx results through infection. If the menstrual outflow be stopped, he believes that increased tension, especially in the abdomen, may produce hemorrhage into the tube or a hæmatoma between the lamellæ of the omentum majus, for instance, or intramuscular extravasations of blood. It must be stated, however, that in such rare cases, with no infectious agent present, no peritonitis results if the contents enter the abdominal cavity. Hæmatosalpinx originating according to the theory of Mainzer constitutes the *transitory form*. It must be remembered that normal blood, normal as to salts and serum, causes no adhesions. Therefore, perisalpingitic affections may be caused by blood mixed with abnormal secretions from the genital canal. This thickened blood forms thrombi and a local chronic adhesive peritonitis. Therefore, the cases of Veit which produce peritonitis are of this character, and if the contents of like cases enter the peritoneal cavity they, for this reason, produce peritonitis. They constitue the *stabile* form and represent irritation tumors which must be treated by operation. The form described by Mainzer may heal through opening of the atresia, and if the contents are pressed by the tube into the abdomen healing may result. Of course the long existence of a transitory hæmatosalpinx may change it to the stabile form, and after emptying the hæmatocolpos and the hæmatrometra the hæmatosalpinx may persist.

A hæmatosalpinx occurs as readily with an atresia in the lower part as with an atresia in the upper part of the vagina. It may occur after a long existing atresia or after a short period. The hæmatosalpinx is not due to the backward movement of the blood from the uterus into the tube, for a hæmatometra may exist without a hæmatosalpinx, as was found in one case after six years of molimina.

With double genital canal, there may be molimina with much menses or without any connection with menses, *i. e.* with atresia there may be molimina (1) without blood; (2) with blood, or there may be; (3) blood without molimina. The earlier the vagina is emptied the fewer are the tubal changes through pressure or necrotic processes.

If with a hæmatometra and a simple genital canal there is no hæmatosalpinx, it is then an atresia,

either (1) intrauterine, due to epithelial union occurring intrauterine, or (2) extrauterine, due to a post-natal cause which does not extend upward. In double formation hæmatosalpinx is a proof that here, too, an atresia may be acquired.

The view of Pincus is as follows: If with molimina menstrualia, in place of the normal menstruation, vicarious hemorrhage occurs (urethra, rectum, lungs, stomach, mouth, nose, and eyes), it is necessary to think of an atresia of the genital canal. Is an atresia present, it is possible that as a result of vicarious hemorrhage into the tube, a hæmatosalpinx is present. Just such cases complicated with vicarious hemorrhages must be treated at once. If molimina occur in spite of plentiful menses or independent of the same, a double congenital canal must be considered.

127 East Sixty-first Street.

CLINICAL NOTES ON A SERIES OF NINE CONSECUTIVE CASES OF ECTOPIC GESTATION.

By HIRAM N. VINEBERG, M.D.,
NEW YORK.
ADJUNCT GYNECOLOGIST TO MT. SINAI HOSPITAL; ATTENDING GYNECOLOGIST TO ST. MARK'S HOSPITAL, ETC.

During my service at Mt. Sinai Hospital in the summer of 1902 I had the good fortune to have a series of nine cases of ectopic gestation, each of which presented some feature of interest or of instruction. Although the profession in general is awakening to the frequency of ectopic gestation, and to the importance of an early and correct diagnosis, the affection has not as yet met with the same alertness on the part of the profession that appendicitis, for instance, has for some years past. It is seldom, nowadays, that a case of appendicitis is not recognized early and promptly, because the profession is on the lookout for it. The same attitude of mind should prevail in reference to ectopic gestation. In this way many lives that are now lost through oversight would be saved, and the attending physician would frequently avoid a humiliating and distressing experience. It is only a few months ago that I was called to see a young woman who had been under the constant care of a very able practitioner for six weeks. He had treated her for a supposed early miscarriage, and a mass subsequently developing in the pelvis, he took this to be a complicating salpingitis. At my visit, on listening to the history of the case, I at once suspected a ruptured tubal pregnancy with repeated intraperitoneal hemorrhages. My suspicions were confirmed on examining the patient, whom I found moderately anæmic, and whose pelvis and lower part of abdomen I found filled with irregular masses of varied consistency. The diagnosis of ruptured ectopic pregnancy was verified at the operation that same night. Owing to the long continuance of the case and the repeated intraperitoneal hemorrhages, there was considerable inflammatory reaction, matting the intestines and omentum to the pelvic organs, and also involving the left adnexa to such an extent that it was with some misgivings that they were left behind. The patient made a slow recovery, and is still the victim of some pain in the left iliac region from the thickened tube and ovary, which, however, have decreased in size very much since the operation. The remorse and chagrin of the attending physician can be readily conceived.

It cannot be too often emphasized (and I may, without egotism, take the credit of having been the first to have done so)* that every case of supposed early miscarriage should be looked upon with suspicion, and one should always bear in mind the probability that it may be a case of ectopic pregnancy.

I shall now briefly relate the histories of the cases comprising the series, commenting upon each in turn:

Case I.—R. Z., aged twenty-seven years, married three years, no children, one miscarriage two years ago, cause unknown. Admitted to the hospital August 16, 1902. Last menstruation occurred three weeks ago. For some time past the patient has complained of pain in the right iliac region. Four weeks ago this pain grew worse, and for two days there was incessant vomiting. The pain has continued.

On bimanual examination the uterus was found to be in a forward position. On the right side of the uterus and posterior to it a resisting globular mass about the size of an orange was felt. Shortly after the examination the patient was seized with a sharp lancinating pain in the lower part of the abdomen. These pains persisted, and about one hour later there was a slight uterine bleeding. On examination the tumor which had been felt before was no longer present; instead one felt a soft, fluctuating, irregular mass filling the pelvis posteriorly and pushing the cervix forward. The pulse became very frequent (104), and was rather small. Dr. M. G. Seelig, the house surgeon, properly diagnosed intraperitoneal hemorrhage, and notified me at once. I responded immediately, and on my arrival found the local condition had changed as above noted. The patient showed marked signs of anæmia. She was at once taken to the operating-room and prepared for laparotomy. On opening the abdomen there was a free escape of fresh blood and blood-clots. The right tube and ovary were seized and brought into the incision, and it was found that the tube was the seat of an ectopic gestation at the ampullar portion. The tube and ovary were ablated, the blood-clots removed as rapidly as possible, and the abdomen closed with tier sutures. The patient rallied promptly and made a good recovery.

In the foregoing case there was no delayed nor irregular menstruation, the *sine quâ non*, according to some authors of ectopic gestation. The menses had been regular, the last regular menstruation having occurred three weeks before admission to the hospital. The patient had had pelvic symptoms for several months, as manifested by pain in the right groin. On examination a semi-fluctuating tumor is found behind and to the right of the uterus. What was more natural than the diagnosis of ovarian disease? It was only after this examination, when symptoms of intraperitoneal hemorrhage were evident, that the diagnosis of ruptured tubal pregnancy was properly made by Dr. M. G. Seelig, the house surgeon. I fully concurred in this diagnosis as soon as I re-examined the patient a few hours after the first examination. The onset of the slight uterine bleeding helped to strengthen the diagnosis.

It is commonly held that uterine bleeding attends the interruption of tubal pregnancy, whether it be through the formation of a fleshy mole, tubal abortion, or tubal rupture. Here in this case it is evident that this rule did not obtain. What was felt at the first examination was, no doubt, a tubal mole, the walls of which were ruptured by the manipulation, giving rise to the subsequent intraperitoneal hemorrhage.

Case II.—M. L., aged thirty years, married eight years, three children and two abortions, last abortion in April, 1902. Admitted to hospital August 11, 1902. Had had an attack of pneumonia eighteen months ago and an attack of rheumatism in childhood. Three weeks ago, when she was two weeks overdue, she had slight uterine bleeding, which

*"Differential Diagnosis between Extrauterine Pregnancy and Early Abortion," Medical Record, November

lasted two days. Some days later had cramp-like pains in the abdomen, which continued off and on for eight days. During this time had a slight show for one day. Since that time she has felt nauseated and rather weak. For the past few days she has again been spotting off and on. On bimanual examination a mass, size of a closed fist, is felt behind and to the right of the uterus. The diagnosis of ruptured tubal pregnancy was made.

On opening the abdomen some free blood was found in the peritoneal cavity, and in addition, a number of soft black clots in Dougles' cul-de-sac. The right tube was found to be the seat of the ectopic gestation. It and the corresponding ovary were removed. The left adnexa were found bound down by adhesions, which were separated and the adnexa left intact. The peritoneal cavity was cleaned of the clots and blood as well as possible and the abdomen closed. The patient made a good recovery.

Here we had a case presenting the classical symptoms of ectopic gestation; delayed menstruation, then irregular uterine bleeding, cramp-like pains in the abdomen, and an irregular mass to the side and behind the uterus. Unfortunately, instead of such cases being the rule, they form the exception, as will be noted in this series.

Case III.—M. S., aged twenty-six, married seven years, three children, last child four years ago. No miscarriages, menses regular, the last occurring ten days prior to entering the hospital. Two days ago had a slight show, which continued for two days. Three weeks ago began to complain of stabbing pains in the right iliac region, which have persisted with more or less severity ever since. She has had no vomiting or nausea. Yesterday noon had a distinct chill. The patient looks ill; the superficial mucous membrane very pale. Tongue moist and slightly coated. Temperature, 101.4°, pulse 96. The abdomen is considerably distended and tympanitic everywhere. The uterus is moderately hard and is in a forward position. Behind the uterus one can feel a non-fluctuating mass, the size of a hen's egg, which is rather sensitive to the touch. A probable diagnosis of ectopic pregnancy was made.

On opening the abdomen the right tube was found to be the seat of the ectopic pregnancy, and a considerable quantity of free blood was found in the general peritoneal cavity. The right tube and ovary were ablated, the patient making an uneventful recovery.

In this case, as in Case I, there was no delayed menstruation, but two days before admission and eight days after the last menstruation there was some slight uterine bleeding. We were then having such a run of cases of ectopic gestation in the ward that, on the strength of this and on the local findings, the house surgeon made a tentative diagnosis of extrauterine pregnancy, a diagnosis in which I concurred. The stabbing pain, the fever, and the abdominal distension pointed rather to an inflammatory process. The one symptom which was in favor of the diagnosis of ectopic gestation was the slight bloody show. Still, uterine bleeding may also accompany a salpingitis. In another case presenting an exactly similar clinical picture, we might, on the other hand, find diseased adnexa. There is no pathognomonic sign or symptom to differentiate the two conditions under such circumstances. It is better in such a contingency to give the patient the benefit of the doubt and open the abdomen. It ought to be noted that the abdomen gave a tympanitic note, and still when the abdomen was opened, a considerable amount of blood was found free in the peritoneal cavity. It is only when the collection is very large that the flanks give a dull note on percussion.

Case IV.—Mrs. C. B., aged thirty-five years, married sixteen years, two children, last child thirteen years ago. For years menses irregular as to time and as to duration; they recur every three, four, or five weeks, and continue off and on for from four to seven days. Seventeen days ago began to have uterine bleeding. The preceding menses had recurred after an interval of four weeks and five days, but was decidedly more scanty than usual. During this period of uterine bleeding she has had more or less pain, but not of a severe character. Four days ago, however, she had severe cramp-like pains in the lower part of the abdomen and in both iliac regions. The pain now is referred chiefly to the right iliac region. Has had no vomiting nor nausea. On admission her temperature was 101° F., and pulse 96. On bimanual examination some fulness was made out in the right vaginal fornix. In front and to the right of the uterus a mass the size of an English walnut was detected, and it was quite tender to the touch. The uterus was of normal size and in normal position. A probable diagnosis of ectopic gestation was made.

At the operation the right tube was found ruptured and the seat of the pregnancy, and as the appendix was found to be adherent to the tubal mass, it was also removed. The patient made a slow recovery, as an exudate had formed about the stump which did not readily absorb.

The difficulty in this case in arriving at a conclusion was the irregularity of the menstrual period normally. The patient seemed to attach no importance to the irregular and protracted bleeding which had now been going on for seventeen days. She said such an experience was not unusual with her. It was only because we suspected ectopic pregnancy that we ascertained on repeated questioning, that the menstrual period prior to the onset of the present flow was more scanty than usual. Only those who have to deal with a similar class of patients will fully realize the difficulties encountered in obtaining anything like a reliable history from these patients. And it is just in ectopic pregnancy that an accurate history is of such great value as an aid in the formation of a correct diagnosis.

Case V.—F. G., thirty-eight years old, married eighteen years, eight children, last child fourteen months old. No miscarriages. Menses set in at the fourteenth year, four-weekly type, amount moderate, duration two to nine days, not attended with pain. About two weeks ago she began to bleed after a cessation of menstruation for nine weeks. Shortly afterward she began to suffer from some abdominal pain, backache, chilly sensations. She was then admitted into one of the larger hospitals in the city, where she was curetted, presumably for a supposed miscarriage. She remained in this hospital for about ten days, and her friends had her then transferred to Mt. Sinai hospital, where she was admitted July 5, 1902. Her condition on admission was as follows: Moderately anæmic, coated tongue, temperature 102.6°, pulse 112, abdomen moderately distended. On bimanual examination the uterus was found pushed forward against the symphysis by a large irregular mass, which filled the pelvis posteriorly and extended upward midway to the umbilicus. The mass was fluctuating in some areas and in others was slightly nodular.

The diagnosis of a large hæmatocele, the result of a tubal pregnancy, was made. The case was considered a suitable one for vaginal section and drainage. Accordingly, a good-sized incision was made in the posterior vaginal fornix and a large quantity

of dark, tarry blood, with numerous dark blood clots, was evacuated. I passed my hand into the cavity and found projecting from its upper wall on the left side a soft fleshy mass, about the size of a hen's egg. Blood in considerable amount seemed to be coming from this mass. I packed the cavity tightly with iodoform gauze and hastily opened the abdomen from above. The blood sac had thick friable walls, and was shelled out with some difficulty. The mass felt from below proved to be the ruptured left tube with a partially organized blood-clot adherent to its interior. The tube and ovary were ablated. The right tube was now investigated and found to be changed into a hæmatosalpinx the size of a hen's egg. It was also removed. The uterus was ventrofixated, and the space behind the uterus was tightly packed with iodoform gauze, the end of which passed into the vagina through the original incision. The abdomen was closed with tier sutures. The patient made a rapid and satisfactory recovery, leaving the hospital twenty-one days after the operation.

This case formed another instance of an ectopic gestation being mistaken for an early miscarriage, the error this time being committed in a prominent hospital. The error, no doubt, was recognized before the patient left the hospital, but the patient had lost confidence in the attending gynecologist and would not remain to submit to further surgical intervention. The case is instructive also as indicating the best course to pursue in similar conditions. When a large hæmatocele, the result of a ruptured tubal pregnancy, is subjected to vaginal incision, the incision should be of good size, so as to admit of a thorough exploration of the cavity with the fingers or hand after it has been emptied of its blood and clots. When a semi-organized mass is found adherent to the wall of the cavity, no time should be lost in opening the abdomen from above and following the course pursued in the above case. When such a course is not adopted there is great danger from subsequent hemorrhage, and should that danger be averted the patient's convalescence is very tedious, and ultimately she may need to be subjected to laparotomy before a cure is established. One should make it a rule, therefore, never to open a pelvic hæmatocele through a vaginal incision without at the same time being prepared to perform a laparotomy should the exigencies of the case demand it. A prominent Fellow of the American Gynecological Society reported at one of the meetings of the society a case of fatal hemorrhage which he had had from opening such a hæmatocele through a vaginal incision.

Case VI.—S. R., aged twenty-two years, married seven months, admitted July 1, 1902. Menses appeared at fifteenth year, regular four-weekly type, amount scanty, not attended with pain. Has never had any pelvic symptoms. No leucorrhœa. Seven weeks ago had skipped her period for one week, when she had a slight show, a mere spotting, but without any pain. A week later she had what she considered as her normal menstruation, though the amount was more scanty than usual. A few days later the slight bleeding appeared again and continued off and on until her admission to the hospital. About four weeks ago—that is, three weeks after the onset of the first bleeding—she was seized with severe cramp-like pains in the abdomen, which have persisted with more or less severity until now. The pain is referred chiefly to the left iliac region. The patient was moderately anæmic. On bimanual examination the cervix was found rather soft, the body of the uterus could not be definitely outlined. To the left of the uterus was an indefinite mass, somewhat sausage-shaped and moderately sensitive. There was considerable resistance on that side, so that a satisfactory examination could not be made. Temperature on admission was 101.4°; pulse, 96.

The diagnosis lay between an ectopic gestation and an early miscarriage, with inflammatory disease of the left adnexa. On July 2 I made a posterior vaginal section, and finding old blood-clots, the wound was packed with gauze and a laparotomy was performed. The ruptured tube, surrounded by a blood-clot, was firmly adherent to the posterior aspect of the left broad ligament. It and the corresponding ovary were removed with considerable difficulty and the abdominal wound closed with tier sutures. The patient made a satisfactory and uneventful recovery.

Taking all the evidence into consideration in the above case, the normal menstrual history prior to marriage, the onset of the symptoms so soon after marriage, the elevation of the temperature, the probabilities seemed to be in favor of its being a case of early miscarriage, with gonorrhœal infection of the left adnexa. It is in just such a case that the value of a posterior vaginal section for the purpose of diagnosis is so evident. For had it been only a miscarriage with gonorrhœal infection of the left adnexa, the removal of the left adnexa would not have been indicated, for such moderate disease can usually be cured by other than surgical means.

Case VII.—B. H., twenty-four years of age, married two years, was admitted July 2, 1902. Her only child was seven months old and she was nursing it. When the baby was two months old the menses reappeared. June 27, when she was thirteen days overdue, she began to bleed slightly, and since then almost every day there has been a slight show. It is only within the past twenty-four hours that she has had any abdominal pain, which she describes as resembling labor pains. Her temperature on admission was 102.6°; pulse, 160. She was extremely exsanguinated, the superficial mucous membrane being blanched. The abdomen was moderately distended and gave a distinctly dull note in both flanks. On placing her on the side the dulness of the flank was replaced by a tympanitic note, giving unmistakable evidence of free fluid in the peritoneal cavity. The patient was at once subjected to a laparotomy. When the abdomen was opened a large stream of blood gushed out with some force. The left tube, which was the seat of the rupture, was quickly grasped, clamped, and removed. The liquid blood and clots were mopped up as rapidly as possible and the abdomen quickly closed. While the operation was in progress one of the staff gave an intravenous saline infusion. The patient, although almost pulseless for a time while on the operating table, rallied promptly within a few hours. She made a slow recovery, convalescence being complicated by a pleuritis on the right side, which gradually disappeared under palliative treatment.

This case presented the classical symptoms of ruptured tubal pregnancy, and as an indication of how rarely cases present the classical symptoms, we must note that this is only the second one in the series. It is apparent, therefore, that the type described in the textbooks and frequently by writers, forms the exception rather than the rule. The case is of further interest in reference to the question whether such cases should be operated upon at once or operation be deferred until the patient rallies somewhat from the great loss of blood. On general principles, the course pursued in this case should constitute the rule; that is, when you have a bleeding vessel, to lose no time in cutting down and securing it. Still, there are times when

it is more prudent to wait for a few hours to see if the patient will rally somewhat. If one sees the patient very shortly after the intraperitoneal hemorrhage, and the collapse appears to be due rather to the impact of the blood upon the peritoneum than upon exsanguination of the patient, it seems to me a short delay would be advisable under these circumstances. I frankly confess that I have never met with such a contingency, but other operators have, and hence the apparent conflict of opinion regarding this point. In the advice given as to when to operate in these cases, one point which to my mind is very important, is frequently overlooked, and that is the contents of the tube are not always sterile. Hence, if considerable time elapses between the pouring out of the tubal contents into the peritoneal cavity before the operation is done, a general peritonitis has had time to develop and the patient dies, not from the loss of blood, but from the peritoneal infection.

I had two such cases about three years ago. Both patients were not seen by me until two or three days after the copious intraperitoneal hemorrhage had taken place. They were exsanguinated to the highest degree, and so anæmic were the tissues that on cutting through the abdominal wall there was not even a sign of the smallest bleeding point. Both rallied from the loss of blood by the administration of intravenous saline infusions and stimulating rectal enemata, but only to die from forty-eight to seventy-two hours later, from general peritonitis, which was present at the time of operation.

Case VIII.—R. S., aged twenty-eight years, married seven years, admitted August 10, 1902. Menses set in at the thirteenth year, regular four-weekly type, amount moderate, not attended with pain. Has one child six years old. Has not had any miscarriages. Two years ago she says she had similar attack to the present. She then went two weeks overdue, when she began to bleed and had severe pain in the left iliac region. An operation was proposed then, which she refused. Had remained well until the present illness, which began two weeks ago. She was then two weeks overdue; that is, she had not menstruated for six weeks. The present attack set in with severe abdominal pains, but they were not severe enough to confine her to bed. About six days ago the pains were very severe for two hours, and now for the first time she had a slight show. The pains and the spotting have continued until the present. The patient was not anæmic and her general condition was good. Her temperature was 100.6°; pulse, 96.

On bimanual examination the uterus was found in a forward position and of about the normal size. To the right of the uterus and rather high up was a small mass, about the size of a hen's egg, which was hard to the touch and rather tender. The house surgeon, Dr. M. G. Seelig, made the diagnosis of ectopic pregnancy, and I concurred in the diagnosis after seeing and examining the patient.

When the abdomen was opened considerable free blood, together with clots, was found in the peritoneal cavity, due, no doubt, to rupture of the tubal fleshy mole during the pelvic examination by several of the staff. The right tube was found to be the seat of the ectopic sac. It and the corresponding ovary were removed, the patient making an uneventful recovery.

The noteworthy feature of this case is the attack two years prior to the present one, and which the patient said gave rise to exactly similar symptoms. There was a difference, however, in that the uterine bleeding was decidedly more profuse, and, as she stated, several blood-clots were expelled. The probabilities are that what she had then was an early miscarriage. However, the profuse uterine bleeding must not be taken as a pathognomonic sign between an early miscarriage and the bleeding which usually attends rupture of an ectopic gestation, as has been done by some writers. I have seen as severe uterine hemorrhage accompanying the latter condition as would occur in any case of uterine miscarriage. Still, as a rule, the bleeding attending a tubal pregnancy is slight, and one of its characteristics is that it is seldom continuous; it comes and goes, and may entirely cease for one or two days at a time.

Case IX.—N. L., aged thirty years, was admitted July 2, 1902. Married eleven years, has one child eight years old. Has had several miscarriages, which she brought on. I had occasion to curette her twice for sepsis following two of the miscarriages. Last one two years ago. Frequently when she would skip a period for a day or two she was in the habit of passing an instrument (or having some one pass it for her) into the uterus with the much-wished-for result. In the latter part of May—that is, about six weeks before her admission into the hospital—when she was three weeks overdue, she took medicine to bring on her menses. A scanty flow did set in. This continued for about two weeks, but not being satisfied with the amount, she had an instrument—probably a sound—passed into the uterus. This brought on a good flow, corresponding in amount to that which she had had with former miscarriages, and she felt that she had gotten rid of her pregnancy. The flow ceased entirely June 20 and has not returned since. She has had absolutely no pain until the attack of illness on the day preceding her admission into the hospital. This attack was as follows: She had partaken rather generously of lobster salad on the night preceding, and felt somewhat nauseated on the next morning when she awoke. But as the day wore on the nausea disappeared. For luncheon she had eaten some cheese cake. She had scarcely finished eating when she felt faint, and soon passed into a condition of syncope. A medical friend who happened to be in the house at the time on a friendly visit gave her several stimulating hypodermics, and in the course of a few minutes she rallied and then vomited. When she was fully restored to consciousness she complained of the most agonizing pain in the region of the epigastrium and right hypochondrium. The pain was so severe that she was unable to move, and it was only after a hypodermic of morphine had been given that she would suffer any one to remove her clothes and put her to bed. On the next day she was brought to the hospital in an ambulance.

I saw her shortly after she was admitted. She was not anæmic. Her general condition seemed good. Temperature, 101.4°; pulse, 120, and of fairly good volume. The abdomen was moderately distended and was rather rigid on the right side. She complained of pain chiefly in the right umbilical region, and there was marked tenderness over the region of the cæcum. On bimanual examination the uterus was high up in the pelvis and was not appreciably enlarged. On the right side above the brim of the true pelvis a small globular mass could be distinctly felt, apparently not larger than an English walnut.

I could not make a definite diagnosis; the weight of evidence seemed to be in favor of an acute appendicitis, although ectopic gestation was considered and could not be excluded. In view of the uncertainty in the diagnosis and the apparent abatement of the more violent symptoms, it was thought wise to keep the patient under observation. On the next day (July 3) there was a decided improve-

ment in all the symptoms; the pain was less, the temperature had fallen to 99.8°, and the pulse to 100-104. This seemed to strengthen the diagnosis of appendicitis, and I was beginning to entertain the hope that operative intervention could be deferred until the so-called interval operation could be done. On the morning of July 4 (that is, one day later), while making a rapid tour of the ward preparatory to my leaving the city for the day, I was struck with the patient's changed appearance. She looked decidedly ill, and she stated she did not feel as well as on the day before. Her temperature had gone up to 103.8°, and pulse to 160. On bimanual examination I could make out that the mass on the right side had somewhat increased in size and volume and was now the size of a small hen's egg. I decided to operate at once. When the patient was on the operating table and was about to be subjected to the usual washing up, one of the attending staff on the surgical side happened to be present and asked permission to examine the patient bimanually, which I granted. He remarked that he could not feel the mass which I said was present, whereupon I re-examined the patient and, to my surprise, could not feel it, either. I stated that the mass had evidently ruptured, and that no time should be lost in opening the abdomen. It did not take many minutes before this was done, and the hemorrhage that I encountered was one of the most alarming that I had ever witnessed. The right tube was quickly caught and clamped, and as the appendix was adherent to the tubal mass, and secondarily involved, it also was removed, as well as the tube and the ovary. It was only by opening the veins in both arms and infusing two liters of saline solution that the patient was made to rally. For several minutes while I was operating the anæsthetist told me that he could not feel any pulse. The patient reacted satisfactorily a few hours later, but her recovery was slow, owing to the profound anæmia and to the development of an exudate about the stump. This, however, completely disappeared in the course of a few weeks, and when the patient was discharged on August 10 she was in good condition, barring a moderate anæmia.

The whole clinical picture in the above case pointed to an attack of acute appendicitis, the indiscretion in diet the night before, the sudden onset, the fainting spell (though the latter symptom is more indicative of intraperitoneal hemorrhage in ectopic gestation, as I have pointed out some years ago), the severe pain at the pit of the stomach, the rise in temperature, and the subsequent limitation of the pain to the right umbilical region, together with the physical sign of decided tenderness in the region of the appendix. The mass felt on bimanual examination could, from its situation, readily have been an appendical tumor. The only suspicious feature was the irregular hemorrhage, but she had denied having skipped a period or having tampered with herself. This was a confession she made only some time after the operation, and even had we known it before the operation the course of events might just as well have indicated an early provoked abortion. In fact, for the two weeks prior to the attack all uterine bleeding had ceased.

In taking a general survey of the cases of the series, one is struck with the feature that in all but two (Cases I and II) there was more or less elevation of temperature. In two cases (V, VII) the temperature had reached 102.6°, and in one case (IX) it rose to 103.8°. It is generally taught that in the differential diagnosis between inflammatory disease of the adnexa and ectopic pregnancy the thermometer is of great aid, in that it usually shows an absence of fever in the latter condition. A series of cases like the foregoing disproves such teaching. It is evident, therefore, that we still have a good deal to learn in ectopic pregnancy, even from the clinical side. Hence the value of such a communication as the present one.

751 Madison Avenue.

MOSQUITOS, QUARANTINE, AND SOME STATISTICS WITH REGARD TO YELLOW FEVER.

By QUITMAN KOHNKE, M.D.,
HEALTH OFFICER OF THE CITY OF NEW ORLEANS.

"Memory, the daughter of Attention, is the teeming Mother of Wisdom, and safer is he that storeth knowledge, than he that would make it for himself."—Tupper.

In the Medical Record of October 25, 1902, there is published an article entitled "On the Eradication of Yellow Fever in Havana," in which the author, Dr. Edmond Souchon, President of the Louisiana State Board of Health, refers to himself as a seeker of truth for truth's sake regardless of its consequences, and closes with the following statement: "This, be it understood, is an expression only of my personal view in the matter." Employed by a man of science in discussing a scientific subject in a scientific journal, such expressions must be regarded as an invitation to other seekers after truth for truth's sake also to express their personal views on the same subject.

While I agree with Dr. Souchon in some minor points, I differ widely from him in his main contention: that quarantine against yellow fever need not consider the mosquito.

Omitting from consideration the proper detention of inoculated persons, I believe firmly that *all* quarantines against yellow fever, in so far as they have been successful in preventing the introduction of the disease, have been so because they presented the entrance of infected mosquitos. Whether this has been accomplished by a detention for a period longer than the life of the mosquito, or by the destruction of the insect in some other way, the *achieving* result has *always* been the excluding of infected mosquitos.

Having thus plainly stated my position, I shall submit the reasons for the faith that is in me, and endeavor to establish in the minds of others its correctness; to do which I must, incidentally, question the correctness of any opinion, differing essentially from my own.

This will be done, in the language of Dr. Souchon, "in no carping spirit of opposition," but in "an effort to establish the real truth."

Dr. Souchon submits a list of epidemics in New Orleans from 1817 to 1899, inclusive, from an analysis of which he makes the following deductions: "Yellow fever in a locality exhausts itself in from two to four years, provided fresh cases, especially virulent ones, are not brought in from the outside, although the material, *i.e.* non-immunes, be still present in the locality. Four infections exhausted themselves in one year, three in two years, two in three years, four in four years, one in five years, and one in six years. Although fresh cases were introduced almost every year, they mixed up with the others, and reinfection took place only when specially virulent cases were imported."

The assertion that infection of the city was aggravated by the introduction of "specially virulent cases," cannot be considered a deduction from statistics, but must be regarded as an opinion only, unsupported by any evidence submitted. It may be correct, nevertheless.

In the newer pathogeny of the disease, however,

virulence would seem to depend upon the number of mosquito-born inoculations or the number of germs introduced into the individual, and his susceptibility, rather than the special virulence of a particular group of germs.

The experiments at Las Animas Hospital during six months of 1891 certainly prove that both mild and severe cases may be mosquito-transmitted from the same patient; and Dr. Guitéras evidently believes that a case may be mild or severe according to the number of germs introduced at the time of inoculation; even though the source of germ supply be a virulent case. I am of the opinion that the early date of its introduction, and the number of mosquitos present—not the special virulence of individual cases—determine the extent of yellow-fever epidemics in the past; and that recrudescence was a lesser factor than is generally supposed.

The vagaries of the quarantine service, fluctuating from one extreme to another, actuated now by an exaggerated fear of infection, and again by powerful influences, directed, perhaps unwittingly, to the interests of commercial circles, may well account for some of the phenomena of yellow-fever visitations improperly attributed to other causes.

DR. SOUCHON'S LIST OF THE EPIDEMICS OF YELLOW FEVER NEW ORLEANS FROM 1817 TO 1899, INCLUSIVE—EIGHTY-THREE YEARS.

Year.	Deaths.	Year.	Deaths.	Year.	Deaths.

Assuming his list to be correct, the Doctor has taken pains to analyze it in his usual careful manner, and has drawn conclusions which can have no application to modern times and modern methods of prevention; not even if the conclusions were based on a true record, which they are not.

Dr. Jos. Jones, President of the Louisiana State Board of Health from 1880 to 1884, reports the number of deaths from yellow fever in 1822 as 808 instead of 239 (the number given in Dr. Souchon's list); in 1829, 900 instead of 215; in 1832, 400 instead of 18; in 1833, 1,000 instead of 210; in 1837, 1,300 instead of 442; in 1839, 800 instead of 452; in 1841, 1325 instead of 594. (Table opposite page 225 of the Report of the President of the Louisiana State Board of Health for 1880). For 1842 and 1843 Dr. Jones gives the number of deaths from yellow fever, in the Charity Hospital alone, in figures corresponding exactly with those of Dr. Souchon for the whole city. (211 and 487). (Table A opposite page 108 of the Report of the President of the Louisiana State Board of Health for 1881.)

It would be absurd to deduct, from the official statistics, that in these two years there was no yellow fever in the city outside of the Charity Hospital, and that it took two years for the disease to spread from the Hospital to any other part of the city, and yet statistics would seem to support such assertions.

Two sets of statistics, differing, cannot both be correct, though both may be wrong; and neither should be accepted as accurate for the period of differing records. No fine deductions can have value, therefore, based upon either list. Records of this kind, even if true, require interpretation to be properly understood. The vital statistics of New Orleans at the present time, if accepted as complete, might be cited to prove that the native population is rapidly dying out; for, while every death is properly recorded, the record of births is absolutely unreliable for purposes of comparison, including, as it does, a small portion only of the number of children born in the city. Statistics are sometimes misleading; for, while no one desires to take them for more than they are worth, it is often impossible to establish their true value.

The comparative absence of yellow fever in New Orleans from 1860 to 1865 would seem remarkable but for the explanation that the commerce of the port was interrupted during the four years of the civil war.

The freedom of this city from yellow fever between 1884 and 1897 has its explanation also; and the statistics of this period, together with the experience of 1898 and 1899, are, perhaps, susceptible of interpretation, by the officially recorded events, more or less connected therewith. Dr. Souchon says, after referring to Dr. W. C. Gorgas's "Mosquito Work in Havana" (MEDICAL RECORD, July 19, page 81): "No one admires more than we do the great efforts and the splendid results obtained by Dr. Gorgas in the sanitation of Havana, but, as a seeker of truth for truth's sake, and regardless of its consequences, it has occurred to us that, although the destruction of the mosquito may have prevented the spread of yellow fever in Havana, the real cause of the *exemption* of Havana and of the island from yellow fever is due truly to the efficient quarantine work of the United States Public Health and Marine Hospital Service officers. They kept out the fever and, therefore, prevented the spread of it by mosquitos or any other cause. The past history of New Orleans bears out this view. Up to the time of the incipiency of scientific quarantine, from 1879 to 1884, there was yellow fever in New Orleans every year, more or less, because the quarantine methods employed up to that time permitted the frequent introduction of cases by vessels without giving the city a chance of exhausting one infection before another infection occurred. Since the inauguration of thorough disinfection of vessels, especially since 1884, under the vigorous championship of our Dr. Joseph Holt, the city has been practically free from yellow fever until the infection of 1897, through the Mississippi coast. It took three years for this infection to exhaust itself, and New Orleans is again free from yellow fever. All that was accomplished without any precautions whatever having been taken against mosquitos."

The last two paragraphs contain two statements: First, that the fever of 1898 and 1899 was a recrudescence of the epidemic of 1897, and, second, that the exemption of New Orleans from yellow fever from 1884 to 1897 "was accomplished without any precautions whatever having been taken against mosquitos."

That the quarantine at Havana was effective, in

that it kept out infected mosquitos, I am satisfied. Fomites could have entered Havana through its quarantine, but mosquitos could not.

In 1884 the quarantine authorities sealed the port of New Orleans under a proclamation of forty days' detention. (Infected mosquitos probably die in quarantine). The one fatal case of yellow fever recorded in that year was one about the diagnosis of which physicians of eminence and special experience differed. In 1885 a plant costing $30,000 was installed by which a system was operated of driving into vessels, by fan power, sulphur dioxide. In 1886 the privilege of entry *without detention* was extended to the fruiters from Central and South America upon the following conditions: The avoidance of infected ports, the employment of acclimated crews; and the non-acceptance of passengers during the summer months. After discharge of cargo the *empty hold of the vessel was fumigated with sulphur dioxide* (mosquitos destroyed). These provisions were enforced until 1895, by which time the trade in bananas, pineapples, and cocoanuts had assumed immense proportions, and had become important both to the steamship owners and the railroads, which distributed the tropical fruit.

To facilitate the trade, and in answer to pressing demands of commercial interests affected, and, doubtless actuated by a laudible desire to remove from commerce burdensome and unnecessary restrictions, the quarantine authorities in this year (1895) passed a resolution *abolishing the fumigation* of the empty holds of fruit vessels, provided they ran only to healthy ports, and were maintained in a cleanly and good sanitary condition. In previous years (from 1886) *all* vessels engaged in the fruit trade were required to undergo fumigation.

The practical operation of the resolution (of 1895) was to permit the *unrestricted and immediate entrance* of fruit vessels *without sulphur disinfection of the hold at any time.* (Mosquitos were *not* destroyed).

If yellow fever is conveyable by these vessels, why, it may be asked, did they not convey it in 1895 and 1896, when mosquitos were not killed by sulphur fumigation? The answer is furnished by the official record (properly interpreted): Yellow fever appeared in the fruit ports in November of 1895 and in October of 1896. (Reports of U. S. Marine Hospital Services).

While our own home-bred mosquitos may withstand the gradual approach of colder weather, a tropical insect, removed from its own to a dissimilar climatic environment, may be destroyed or rendered incapable of mischief.

That we do not fear the introduction of yellow fever, except during the summer, is evidenced by the withdrawal of quarantine restrictions in October. In 1897 the disease was reported in the fruit ports as early as April, and was notably severe. In 1897 we had yellow fever. The epidemic of 1897 has been seemingly traced to various sources. The fact that Ocean Springs, Miss., was infected previous to any known infection of New Orleans pointed, and perhaps truly, to Ocean Springs as the avenue of infection for this city. So many of our people have summer residences on the gulf coast of Mississippi that it is, as far as the intimate relationship may make it, practically a suburb of the city; and it may never be known, as between Ocean Springs and New Orleans, which first infected the other. With the beginning of the epidemics of 1897 and 1898 I was not at the time familiar. In 1899, however, I was in a position, officially, to study the first cases, investigate their surroundings and trace their origin.

The first cases, so far as is known or believed, occurred in the family of a railroad man, employed as a clerk in an office near the I. C. fruit wharf, which he had frequent occasion to visit; and which his children frequently visited. Every member of his family was sick with a fever, whose nature was not recognized, until the symptoms were markedly emphasized in his own person. His case was reported as one of yellow fever on September 1, 1899; his family having been sick some time during August, and having recovered at the time of his attack. Subsequent cases developed in the neighborhood, and for a good while the disease seemed to be confined to a limited area in this section of the city; gradually, however, spreading as the season advanced. In July of 1901 the first appeal was made to the quarantine authorities to recognize the mosquito as a factor in yellow-fever transmission. "This matter," I wrote, "seems to me exceedingly important, and worthy of the most serious thought."

A deeper study of the question sustained my belief in the mosquito theory, and, convinced of the necessity of its thorough application to quarantine, I offered, on September 12, 1901, to furnish to the quarantine authorities "men and material to disinfect fruit vessels pending the consideration of the question." No action was taken on the proposition or the appeal despite repetition and persistent urging. (New Orleans cannot quarantine except by and through the State Board of Health.)

On March 15, 1902, I wrote: "My first communication on the subject was dated July 29, 1901, and on April 1, 1902, the quarantine season will begin. . . . The question under consideration for more than six months seems to be whether or not a pot of sulphur should be burned in the empty holds of fruit vessels to destroy mosquitos, which the very highest authorities most positively assert are capable of conveying, have conveyed and do convey, yellow fever. . . . Sulphur fumigation of empty fruiters was practised during a number of years when this city was free of yellow fever, and the many incidents seeming to connect the tropical fruit trade with the disease in this city compel me to insist that this subject be given the consideration it demands before disaster forces us to realize, too late, the important defect in our quarantine system."

On April 1, 1902, the sulphur disinfection of fruiters (empty) was re-established; to be modified, however, one week later so as to apply to those vessels, only, from ports where yellow fever may be reported. A harmless modification, surely, *if the reports are true, complete, and prompt;* but if they are not—Does the price of a few pots of sulphur justify the risk?

A wrong theory, advanced by the master minds of their day, and for a generation held as true, clings to the understanding with a persistency that disregards the weight of evidence, against which the *ipse dixit* of authority for a time prevails. But in the end all else but truth must relinquish its hold, and drop, at last, into that vast sea of error filled with the conscientious mistakes of the most able and most eminent men.

The Association of Typhoid Fever and Tuberculous Meningitis.—M. C. Chavigny concludes from his studies of the subject, that the association of these two diseases is possible, but that it is extremely rare. The clinical diagnosis is difficult, and can be positively made only by the help of serum-diagnosis. At autopsy the closest attention is necessary, as the lesions of typhoid fever may not be pronounced. In proportion, the symptoms of meningitis are the more marked of the two during the course of the disease.—*Revue de Médecine.*

THE INDICATIONS FOR OPENING THE PARS MASTOIDEA.*

By L. D. BROSE, M.D., Ph.D.,
EVANSVILLE, IND.
OCULIST AND AURIST ST. MARY'S HOSPITAL.

Under "Pars Mastoidea," following Schwartze, we include the mastoid antrum and the cellular spaces within the temporal bone, that are usually in connection with it. The indications for opening these cells necessarily rests upon the symptomatology and diagnosis of the various diseased conditions, for the relief of which it is deemed proper to undertake such operative interference. My paper, then, will properly deal not only with the acute and chronic affections of the mastoid cells and middle ear, but also with those intracranial conditions secondary to them. Of the acute affections we will first consider acute abscess of the mastoid. Pain in and around the ear is one of its most constant symptoms. Accompanying this, there is usually some fever and circumscribed pressure tenderness over the fossa mastoidea, which, according to Bezold,[1] represents the posterior end of the mastoid antrum, and the adjoining mastoid cells, and is to be sought directly under and back of the auricle, and immediately below the linea temporalis. Percussion dulness, an uncertain symptom, may also be sought for. Upon perforation of the drum, and beginning otorrhœa, the pain and tenderness may, in part or wholly, disappear, and again recur at the same point, or by predilection occupy either the anterior or the posterior border of the mastoid protuberance, the points over the greatest development of the superficial bony cellular spaces. With the increase of pain and tenderness, swelling and œdema may occur either over the mastoid or around or in the outer ear. Of especial significance is swelling over the posterior superior bony meatus wall, giving rise to narrowing or total occlusion of the meatus. Fluctuation in the external swelling is to be sought for earlier in the child than in the adult. When the symptoms mentioned have persisted eight to ten days without amelioration, notwithstanding recognized proper treatment has been administered, or when they have wholly disappeared, either with or without closure of the drum perforation, and again returned in severity and persistency, the mastoid operation may properly be performed. Experience, however, is of the greatest value in enabling one to decide when to operate and when not, and it must not be overlooked that in nearly all cases of severe acute, middle-ear suppuration, the mastoid cells contain pus, which, as the patient recovers, is capable of spontaneous resorption. Chronic disease of the mastoid may exist for years without sufficient evidence to warrant operative interference. There is always danger of serious complication, when the chronic ear disease has been occasioned by one of the acute, infectious diseases, such as scarlet fever or diphtheria. Chronic otorrhœa, with existing diabetes, is apt to develop deep-seated mastoid caries. Operative interference is urgent for pus retention that cannot otherwise be relieved. As symptomatic of pus retention, we have a sudden diminution, or total cessation of a profuse ear discharge, narrowing of the meatus or clogging of the tympanic cavity by granulations or polypi, fever, and symptoms of meningeal irritation. External abscess formation with fistulous opening leading into the middle ear or mastoid, especially if occurring in an adult, indicates a mastoid operation. In children, however, when the pus drainage is good, nature alone is frequently capable of bringing about a cure, when assisted by local syringing and improvement of the general nutrition. The growth of cholesteatoma in the temporal bone, and by this I mean an invasion of the middle-ear and mastoid cells by epidermal epithelial cells, their subsequent excessive growth and desquamation, and the formation of epidermis masses often covered with a pearly, glittering coat, may also require removal, through a mastoid operation. Such patients are apt to complain, especially if there is hindrance to the exit of the discharge, of earache, headache, and vertigo, relief being obtained with either the spontaneous or operative removal of the epidermis masses. The diagnosis of cholesteatoma rests upon the detection of such masses in the middle ear or in the otorrhœal discharge. Caries and necrosis may follow either an acute or a chronic inflammation of the mastoid.

As an instance of a rapidly fatal termination following caries with acute mastoiditis, I will recite the following case, for the record of which I am indebted to Dr. Leartus Owen: L. H., a well-nourished individual, about thirty years of age, and whose general health has always been good, developed, about August 22, 1902, after taking cold, an acute abscess of the right middle ear, for which he consulted Dr. E. Walker, and later Dr. A. J. Knapp. The right membrana tympani was punctured, and the ear treated locally. After about ten days of treatment the patient had a chill, followed by rise of temperature to 104°, severe pain in the head, and tenderness at the tip of the mastoid. An operation was suggested, but not made. The patient grew better with the application of an ice cap and antipyretic treatment. Temperature the following day, 99⅔°. The affection of the mastoid continued, but was not severe. The ear discharge showed diplococci in pure culture. At eight o'clock in the evening of September 11, he complained of nausea, dizziness, and headache, the pain being very excruciating, for which three-quarters of a grain of morphine gave but partial relief. He complained also of the left ear, and acted as though there was beginning unconsciousness. Next morning he was unconscious. I saw the patient for the first time about one o'clock in the afternoon of September 12, and in consultation with Drs. Worsham and Ravden. He was in an unconscious state, from which he could not be aroused. An examination of the right ear showed a small opening in the drum, in the upper part of the posterior lower quadrant, on the apex of a small teat-like swelling. The external meatus contained a very small quantity of thin pus, with but little odor. The pupils were semi-contracted, and the temperature about 100°. Externally over the mastoid there was neither swelling nor visible inflammation, but those in attendance assured us it had been markedly tender during the time the patient was rational. The left ear was without signs of disease. The opinion was given and concurred in by Dr. Worsham, that the patient would in all probability die, and that an operation, which the family favored, offered the only possible chance for improvement. An ophthalmoscopic examination had not been made, and because of our not knowing the nature of the patient's ailment and condition, we were not prepared to make one at this our only opportunity of seeing him before the operation, which was done two hours later, by Dr. E. Walker. It consisted in laying open the mastoid cells, antrum, and middle ear, with hammer and chisel. Within the mastoid pus was found, and upon its inner wall a curious opening discovered, through which a probe was passed into the posterior fossa of the skull. The opening was enlarged with the curette,

*Read before the Ohio Valley Medical Association, at the Evansville, Ind., meeting.

and the wound packed lightly with iodoform gauze for drainage. The patient continued during the night in a state of unconsciousness, and by the following morning developed left exophthalmos with dilatation of the left pupil. On the right side there was slight facial paralysis with contraction of the pupil. The temperature was 100°, pulse 106. At irregular times he had paroxysmal opisthotonos. The evening of the second day the pulse came up rapidly to 160 and was irregular. The respiration was labored and 25. Death occurred during the night of September 14. Autopsy made and reported by Dr. Owen. Only a head section was permitted and made, five hours after death. Dura mater congested. Beneath the dura and filling the sulci was a considerable quantity of pus. This was collected principally over the lateral region of the brain on both sides, and over the posterior portion of the base. In each fissure of Sylvius there was pus collection, notably the left with thrombosis of the vessels. The entire pia mater was deeply congested. The lateral ventricles contained an abnormal amount of thick white fluid. The fourth ventricle and pons, normal. The operative opening was found in the posterior wall of the petrous bone, which was necrotic for a considerable distance around the opening. Pus was found in both the posterior and the middle cerebral fossæ. I may add, as the cause of death, suppurative meningitis.

The subjective symptoms of caries and necrosis are very variable. Pain, when present, is a manifestation of periosteal detachment, rather than of bone destruction, and with extensive necrosis little or none may be felt. Especially is this apt to be the case in tubercular disease. A diagnosis of caries is reasonably certain when a fetid otorrhœa resists all treatment and the drum perforation, at the same time, gradually enlarges. The finding in the ear discharge, upon microscopical examination, of bone cells is highly corroborative evidence. Conclusions as to the seat of the disease and its extensiveness are formed by the detection of roughened bone or a sequestrum with the probe, the presence of fistulous opening in the bony external meatus or mastoid, and the manifestation of facial paralysis or labyrinthine disease. Before undertaking an operation for caries, one should recall that the roof of the middle ear at the same time forms part of the floor of the middle cerebral fossa; that the bulb of the jugular vein lies just under its floor; that the carotid canal runs under its anterior wall, and that the canal for the facial nerve runs through the lower part of its posterior wall, while the delicate internal ear labrinth occupies its inner wall. A mastoid operation may be undertaken either as a curative or as a prophylactic measure against involvement of other structures in caries or necrosis of the temporal bone. The prospects for cure are best when the bone disease is limited to the mastoid cells. On the contrary, when it is localized and occupies the floor or inner wall of the tympanum, the mastoid operation is superfluous. Protracted and severe neuralgia of the mastoid, that resists all other treatment, and even when an examination of the ear shows the complete absence of disease, is often curable through a mastoid operation. In all cases in which, during a middle-ear suppuration, symptoms of meningeal irritation or brain abscess, or beginning sinus phlebitis, occur, operative opening of the mastoid is positively indicated. Pachymeningitis externa and extradural abscess may properly be considered together, since the symptomatology, when the former alone exists, is too obscure to warrant a diagnosis. They occur oftener in the male than in the female, and in the majority of instances are right-sided and at the point where most of the blood vessels pass through the mastoid, namely, in the bony groove that lodges the lateral sinus. Large collections of pus may exist between the dura mater and the bone without being suspicioned, and only discovered during an operation for carious or necrosed bone. The symptoms of extradural abscess and pachymeningitis are temporal headache, somnolence, vomiting, fever, slow pulse, and optic neuritis. Politzer[2] attaches much diagnostic importance to the frequent changing appearance and disappearance of threatening symptoms, especially the cessation of severe inflammatory and meningeal irritation after a sudden free flow of secretion from the ear. When the extra dural abscess is in the middle cerebral fossa, especially in children, we may have crossed paralysis and disturbance of sensibility, with speech disturbance in addition if the lesion be a left-sided one. Of great importance are the local symptoms when there is an attempted spontaneous external pus evacuation through either a fistulous bony canal or through the mastoid foramin. Then occur œdema, redness, and swelling, and localized tenderness, either just around the upper border of the auricle, or back of the mastoid protuberance. Leptomeningitis purulenta may run either a very rapid and fatal course, ending in death in a day or two, or assume a more protracted form, with remissions and intermissions of fever, spasms, loss of consciousness and paralysis, until after some weeks coma supervenes, ending in death. The initial symptom is generally a chill, followed by variable temperature, usually high when the convex surface of the brain is affected, headache, frequently of a most violent character, and intensified by straining, cerebral irritation, manifested by excitement, restlessness, vertigo, photophobia, optic neuritis, vomiting, loss of memory, delirium, stupor, coma, tonic or clonic spasm, aphasia, sluggish pupillary reaction, and crossed paralysis. The result of this disease is almost without exception fatal. Of the venous sinuses lodged in the temporal bone, the transverse sinus is by far oftenest involved by inflammation and thrombosis. In the majority of instances the disease can be traced to direct contact of the sinus wall with diseased bone, or an epidural abscess, or to infection transmitted through the small veins that carry blood through the temporal bone, and empty into the lateral sinus. The diagnosis is comparatively easy when, with an existing chronic otorrhœa, we have sudden and severe chills, unusually high temperature, with frequent remissions, so that the temperature falls below normal, and again, in a short time, either with or without a chill, rises to fever heat, followed later by metastases and obstruction in the internal jugular vein, recognizable upon palpation. After some days the skin becomes dry and sallow, the tongue dry and heavily coated, while consciousness in contradistinction to cerebral abscess or meningitis generally remains clear up to a short while before dissolution. Since, however, the most successful operations are made before the disease has lasted long enough to produce such pronounced symptoms, we must seek for its detection as early as possible through local manifestations of circulatory obstruction, such as œdematous swelling over the mastoid and occipital region, Griesinger's symptom; a difference in the blood flow in the two external jugular veins, Gerhardt's symptom; painful infiltration and induration of the connective tissue in the upper part of the neck, Greene's symptom, and œdema and erysipelas of the face and eye-lids on the affected side, Wreden's symptom. According to Macewen,[3]

we may arrange those cases that take an unfavorable turn either with or without operation into three groups, according as the dominant symptoms are pulmonary, abdominal, or meningeal. The pulmonary manifestations are slight dyspnœa, cough, localized areas of pain over the chest, corresponding to the lung metastases, followed soon by rusty sputum and moist râles. Abscess formations and gangrene precede death, which occurs from exhaustion. The brain, as a rule, remains clear until very near final dissolution. The abdominal type presents symptoms of a typhoid nature, dry furred tongue, loss of appetite, offensive diarrhœa, great prostration, and muttering delirium. The meningeal group is least common, and presents continuous high temperature, vomiting, tonic and clonic spasm of the eye, facial or neck muscles, irritability, delirium, great prostration and coma, ending in death. The meningeal group, however, is not a sharply defined one, and along with the meningeal symptoms, we find some of those in association with either of the other two groups. The symptoms of thrombosis of the cavernous sinus are highly characteristic, and consist of engorgement of the orbital vessels, disturbance of sight, neuroretinitis, photophobia, paralysis of the oculomotor and abducens nerves, exophthalmos, ptosis, œdema of the eye-lids, neuralgia, and anæsthesia in the region supplied by the first division of the fifth nerve. Thrombosis of the superior and inferior petrosal sinus runs its course without characteristic symptoms. Otitic brain abscess presents the most advanced phase of mastoid surgery. The diagnosis of this trouble, never easy, is especially difficult in the child, because symptoms of brain irritability are so easily excited in it by diverse causes. It is developed either by direct extension of the suppuration to the brain substance, by continuity, or, as is oftenest the case, without direct communication, and in connection with chronic suppuration in the middle ear. It may also result from traumatism during an existing middle-ear disease. Körner[4] gives the seat of the brain abscess as 63 per cent. in the temporal lobe, and 37 per cent. in the cerebellum. As a rule, you may expect to find the abscess oftenest in that portion of the temporal lobe lying over the tegmen tympani, while the favorite position of cerebellar abscess is either in that part covering in the posterior surface of the pyramid, or in the vicinity of the groove for the lateral sinus. The brain abscess may be single or multiple. A fistulous canal can at times be traced from the caries in the temporal bone to the abscess cavity, and when found simplifies the diagnosis. It is well, therefore, to ascertain the nature and seat of the ear disorder before taking up minutely the brain manifestions. These may be classed as general and local. Under the former we first mention pain. This may occur as a general headache, or be localized over the seat of the abscess. Of considerable importance is localized percussion tenderness over the temporal lobe, either with or without localized temperature elevation. The pulse when brain compression exists is slow, later becoming rapid. Chill and fever are uncertain, but, as a rule, the temperature is never high. Vomiting is usually present at some time during the disease, especially if the abscess be in the cerebellum. General sluggishness, lethargic and slow cerebration may occur as early manifestations with later delirium, weakness of memory, somnolence, and coma. Sensory disturbances are seldom lacking at some stage, while convulsions may occur, and, with the lesion in the temporal lobe, they may remain limited to the extremities and the opposite side of the face. With the lesion in the cerebellum, the convulsions are more inclined to be general. Optic neuritis is far more frequently found than choked disc, the reverse being true in brain tumor. The local brain symptoms are more or less determinative of the seat of the focal disease. With abscess of the temporal lobe, the hearing center for the opposite ear may be destroyed, crossed deafness resulting. Because of somnolence, it may be hard to bring out this symptom. As evidence of involvement of the internal capsule, we have crossed spasm or paresis of the extremities. When the pus cavity is enlarged forward, crossed disorders of sensibility are seen, with, maybe, facio-lingual involvement. Word incomprehensibility, with lesion of the first temporal convolution and the angular gyrus, was found in one case. Speech disturbance is not infrequent with left-sided temporal lobe abscess. Partial involvement of the oculomotor nerve, especially of the fibers going to the pupil and upper lid, resulting in mydriasis and ptosis, has also been found in connection with abscess of the temporal lobe. The abducens nerve, on the side of the lesion, has also been known to suffer. True motor aphasia has not been observed in uncomplicated cerebral abscess. Focal cerebellar abscess, especially if in the neighborhood of the vermiform process, is associated with general convulsions, crossed tonic spasm, such as rigidity of the cervical muscles, cerebellar ataxia, and vertigo. Facial paralysis and respiratory disturbance may likewise occur.

HOT DECINORMAL SALT SOLUTION INJECTIONS IN THE TREATMENT OF HEMORRHOIDS.

By LUCIEN LOFTON, A.B., PHG., M.D.,
BELFIELD-EMPORIA, VA.
EX-PRESIDENT SEABOARD MEDICAL ASSOCIATION OF VIRGINIA AND NORTH CAROLINA.

I BELIEVE I am the first surgeon to report and advise the hot decinormal saline solution injection in the treatment of piles.

In April, 1900, there came to my office a negro woman, aged forty years, weight 125 pounds, who was suffering greatly with both external and internal hemorrhoids, and whenever her bowels became constipated quite a great deal of pain was experienced, as is usually the case, besides some blood accompanied the act. She was thoroughly examined, and I advised operation, but she being opposed to it, I concluded I would try the pure phenol solution instead, which I attempted, but, unfortunately, on account of accidentally dropping a little of the acid on the external parts, she asked that I use something "not so strong." The thought came to me to try the hot saline solution, as I had had a few days previous experienced considerable uneasiness while using the pure phenol on a Mr. Gray, a carpenter of this city, in whom I injected thirty drops of the pure phenol solution, and within ten minutes I had a case of carbolic-acid poisoning to fight. I have since concluded I must have punctured a vein, as I had used the identical dose on this patient before, without the slightest toxicity. Remembering this, I suggested to the woman that I use some water, and at once sterilized a decinormal salt solution. From one to two and a half drachms of this liquid was injected in each tumor (there being eight in all) as *hot* as could be borne by my fingers, *i. e.* to merely dip the

end of the finger in the water and hurriedly remove it. Eight sacs were thus treated in the following manner: Thrusting a very sharp and keen needle approximately half way through the tumor, I pushed in ten drops, waited a second or two, pulled out the needle about a sixteenth of an inch, and placed ten more drops, the final amount being placed simply beneath the mucous surface, which almost immediately turned a pink-red color, but within a minute or two became blanched. Attacking the tumor at a more convenient point, I repeated the identical procedure, being careful in keeping the water as hot as possible—in fact, if I had not been afraid of bursting the glass barrel of my syringe, I would have injected the solution boiling hot. Strange to relate, the woman experienced little or no pain from the hot water; the only inconvenience felt was the prick of the syringe needle. I instructed the patient to return to my office in two days, giving her to take the night following the day of operation three compound cathartic pills, which I learned acted nicely, and without pain. The woman remained in my waiting room a half hour after the original experiment, that I might ascertain, if possible, the immediate effect of the injection. Upon leaving, she said walking did not cause the slightest pain, but said she felt a fulness or pressure not unlike a person feels when the bowels want to move. Other than this, no inconvenience was noted. She lived about three miles from my office and *walked* the entire distance, during which, she told me, she attempted to have a passage, which resulted in her discharging some blood. She furthermore said that when seated she had perfect relief from the pressure. Next day she worked in the field as usual, with practically no sensation of pain. I go into minute details to give the reader the full benefit of the initial experiment. On the third day she walked back to my office, and appeared brisk and lively. Upon examination, the external tumors looked a trifle more congested than at first, but upon pressure there was less pain than before the operation. The woman being placed in the Sims' position, I explored the rectum with a small speculum, and about the same general condition obtained inside, with the exception that the bags were flattened more than previously and appeared soggy. Upon moderate pressure, serum and blood oozed out in small quantities from each tumor. I particularly inquired, when I pressed a probe, armed with absorbent cotton, on the sacs, if it did not give her pain. She answered in the negative. Cleansing the inner site of operation with a probe wrapped with lint, I gave the internal piles the same treatment as was given originally, but at different points from the first, confining my operations nearer the base of each projection and along the apex. This solution was boiling hot, as I had secured an all-metal hypodermic syringe during this interim. Each tumor was given the same amount of liquid, but a larger quantity was used in each than previously. If I remember correctly, two drachms of the decinormal salt solution was thrown in and around each bag this time. The outside growths were flooded in the same manner. At this sitting the mucous membrane, owing to the greater amount of heated water, readily blanched, and remained so for fifteen minutes, after which a state of local congestion or stasis came on. No appreciable inconvenience was noted during this treatment other than a full feeling about the rectum. She was given a bland ointment and told to apply it daily, internally and externally, and to keep the bowels in a soft, mushy condition with the compound cathartic lisp, *i. e.* by taking from two to four each night or every second night at bedtime, or as conditions demanded, and was instructed to report in a week, which she did. She now walked with some uneasiness and said, before getting on the operating table, that her rectum felt somewhat sore and that around her anus a moist condition prevailed. An examination revealed every tumor in a state of slough, and a number of pieces were readily pulled away with a pair of hæmostatic forceps, without causing any hemorrhage or pain. Two of the internal sacs came away *in toto*, simply by snipping a twig of putrid mucous membrane. The parts were trimmed up nicely with a pair of curved scissors, and a piece of borated gauze, anointed with carbolized vaselin, wound into a wick the size of the index finger and about three inches long, was inserted into the rectum. On the external surfaces the same ointment was applied minus the gauze. The woman was given instructions to remove the gauze in about twenty-four hours, or sooner if necessary, on account of defecation or pain, but to insert with the index finger a piece of the salve about the size of a small pecan nut nightly, and to keep the outside parts well lubricated. The pills were omitted for four days, and the woman was placed on a liquid diet of milk, broths, and thin soups. In four weeks from the last visit the general seat of operation was clear and nicely healed, resolution ending in no disturbing cicatrices or any unusual contraction, the lumen of the gut being fully and completely restored.

I saw this patient and examined her a few weeks ago. She has had two children since. She now enjoys capital health. Her rectum is free from all hemorrhoidal excrescences, and a permanent cure has been effected.

Altogether, I have treated seventeen cases of both internal and external piles by this method, varying in size from that of a peanut to an English walnut, and from a half to one and a half inches in length, with the same general good results. The question arises, how is a cure effected? We all fully recognize and acknowledge that boiling water will burn the flesh as effectually as fire, steam, or electricity, and that when cool or cold influences are eliminated the heat is greater, consequently the scald is more severe; then we are forced to the conclusion that this is a simple scalding process, which acts as does an escharotic; hence, a sloughing process must follow, resulting finally in elimination, followed by granulation and a cicatrix. Owing to the great heat incorporated in this method when the preparation is thrown under the skin, the albumin of the blood is immediately coagulated, and thus we have a circumscribed area of tissue walled off.

The method I have outlined is simple, cheap, effective, non-toxic, and always safe, and I trust the profession will give it proper and just consideration, whenever possible.

Finally, it might be well to state that boiling water thus used seems to act in a measure as a local anæsthetic; the insensibility lasted in some instances several minutes. In experiments upon my own arm, I found that no appreciable pain resulted even when the water was boiling hot, but a subsequent slough was narrowly averted.

This mode of utilizing hot salt water opens up a new field in piles and special surgery. While salt was selected as a mild antiseptic, other substances more pronounced in their action may be substituted, not only in the above condition, but wherever and whenever we desire certain destruction of abnormal tissue.

New York, March 14, 1903.

ABOLITION OF THE OFFICE OF CORONER.

THERE is now before the Legislature of the State of New York a bill to abolish the office of coroner and transfer its duties to existing municipal departments. This bill originated in the New York County Medical Association. The object of the bill is to reorganize the system of verification of deaths from unknown causes so as to render this important service more prompt, more efficient, and more economical.

Briefly, first, the bill transfers to the Health Department the initial proceeding of determining the cause of death or whether there is connected with the death a suspicion of crime. This is one of the most important duties of the Health Department and is at the foundation of its highest and most important service in the public interest, viz., the protection of the public health. It is of the utmost importance to the success of the Health Department that the exact cause of every death should at once be known, for on that knowledge will depend its power to prevent similar fatalities. The determination of the exact cause of death in the cases in which the cause is unknown requires expert knowledge of pathology and laboratories for chemical and biological investigation. The Health Department of this city is amply supplied with all the requirements necessary to render the verification of deaths from all causes very prompt and scientifically accurate. But under the coroner's system, as at present organized and managed, all cases of uncertain death must be sent from the Health Department to those officials who have neither training nor the equipments necessary for exact and reliable investigations. The result is that in many cases there has been a complete miscarriage of justice owing to tardiness in the proceedings, or want of expert knowledge, or lack of proper facilities for scientific work.

The second notable feature of the bill is that which imposes upon the District Attorney the duty of conducting all legal proceedings connected with the inquest, which is to be held in the magistrate's court. The object of this section of the bill is to secure a far higher grade of ability and much greater efficiency in the legal proceedings when there is a suspicion of crime developed in the investigation of the cause of death, for the District Attorney will have a representative of his office present at all the stages of the investigation. When the medical examiners have determined that there is a suspicion of crime the case at once passes to the jurisdiction of the District Attorney, who proceeds to conduct the inquest before a magistrate, the medical examiners appearing as expert witnesses. This change in the present system gives to every stage of the inquest that precision and dignity that such a public function demands.

It must be evident to every one that a system of verification of deaths, as proposed in this bill, by the Health Department, and the subsequent inquest conducted by the District Attorney before a magistrate, must give to all legal and judicial proceedings in such cases that character and reliability which their importance necessitate. Neither must the economical view of the case be lost sight of. By utilizing the existing municipal organizations there would manifestly be a great reduction of expenses. The coroners of the Greater New York receive in salaries alone the enormous sum of $61,000, while it requires an additional $90,000 to pay the high-priced clerks, stenographers, physicians, etc., the total cost of this antiquated system being for the current year $151,300. The bill in question would reduce that amount from one-half to two-thirds and give infinitely better results.

Finally, if this bill becomes a law it will forever remove this very important service from the touch and contamination of politics. The only opposition which the measure has encountered, or is likely to encounter, is from professed politicians. We trust there is a sufficient number of members of the Legislature, independent of the persuasion and dictation of machine politics, to enact the bill into statutory law. We have no disposition to criticise the present coroners, for they are as competent as the method of selection by political parties will admit. It is the vicious system itself, which most civilized communities have long since abolished or reformed, that we wish to see reformed in the interests of science and a sound public policy.

THE LOCAL BOARDS OF HEALTH BILL.

THE bill to amend the public health law relative to local boards of health introduced in the Senate of New York State by Mr. Stewart, is well calculated to institute many much-needed reforms of present systems. Heretofore the local health boards have been managed on very loose principles of coördinate action with the State board, and the growing necessities for uniform action and proper centralization of executive power are alarmingly apparent.

In the larger cities the regulations are stringent enough to guard against the inroads of contagious and infectious diseases, but the country towns and rural districts are at the mercy of primitive regulations which, inefficient as they are, are seldom enforced. A recent and striking object lesson in point is the history of the recent typhoid epidemic at Ithaca. It is seemingly more particularly to meet such conditions that the bill in question has been framed. The general object of the measure is to make the local boards more directly and legally responsible for their acts.

In the matters of proper legal control of sewerage and stream pollution no regulations can be too strict or too comprehensive. Therein rests one

of the fundamental requisites for the arrest and prevention of typhoid fever. In this connection it may be well to suggest to our legislators that it should be made obligatory on physicians to report all their cases of such fever the moment a diagnosis is made. This is required of the practitioners in the larger cities, and there is no reason why similar laws should not apply to those in the rural districts and smaller towns. Everything depends upon knowing of the initiatory cases and in taking prompt preventive measures.

Another matter bearing on stream pollution should also receive direct attention. As contaminated oysters are a frequent cause of a typhoid-fever epidemic, there should be some rider in the law forbidding the planting of these shellfish at the mouth of sewers for fattening purposes. No dealer, for instance, should be allowed thus to endanger the lives of his customers, under heavy penalties. The State board could be given ample jurisdiction in the matter without in any way making unreasonable restrictions upon the industry in question.

The bill, however, even as it stands, is a most excellent one, and, with the State medical associations behind it, bids fair to become a law. It certainly deserves all the support it can obtain from the profession of the State.

DIET OF THE INSANE.

In an editorial article that appeared in the Medical Record, February 21, commenting upon the last annual report of the State of New York Charities Aid Association to the State Commission in Lunacy, attention was drawn to that part of the report in which reference was made to the diet of the patients in the New York State hospitals. It would be an almost impossible task to formulate a diet table best adapted to the requirements of asylum inmates suffering from the various forms of insanity. But, at the same time, all authorities agree that in the majority of cases a generous amount of food is strongly indicated.

In June, 1893, Prof. Austin Flint was requested by the New York State Commission in Lunacy to prepare a report on dietaries and food supplies for the guidance of the State hospitals in the preparation of monthly estimates under the operation of the State Care Act, which was to take effect October 1, 1893. Dr. Flint's revised report was published by the commission in 1894. The following schedules were therein recommended: Daily ration—Meat, with bone, including salted meats, fresh and salted fish, and poultry, 12 ounces; flour to be used in making bread, and in cooking (may in part be substituted by corn meal and macaroni), 12 ounces; potatoes, 16 ounces; milk, 16 ounces; one egg; sugar, 2 ounces; butter, 2 ounces; cheese, 1 ounce; rice, hominy, or oatmeal, 1½ ounces; beans or peas (dried), 1½ ounces; coffee, ⅝ of an ounce; tea, ⅛ of an ounce. Schedule 2.—Supplies for one hundred persons for thirty days: Meat, with bone, including salted meat, fresh and salted fish and poultry, total, 2,250 pounds; flour, 2,250 pounds; potatoes, 2,250 pounds; milk, 1,500 quarts; eggs, 250 dozen; sugar, 375 pounds; butter, 375 pounds; cheese, 188 pounds; rice, hominy, and oatmeal, 282 pounds; beans or peas (dried), 282 pounds; coffee, 156 pounds; tea, 24 pounds.

With reference to this table, Dr. Flint says, "This table should be regarded as very elastic. I think experience has shown it to be more than ample, and that considerable saving may be made, especially when fresh fruits and vegetables are available at low prices. Keeping in view always a proper variety of food, all the articles should be considered interchangeable in quantities to about equalize the cost. Flour should be interchangeable, on this basis, with potatoes, rice, hominy, and oatmeal. Butter and cheese may be interchangeable in the proportion of one pound of butter to two pounds of cheese; and eggs and milk in the proportion of two eggs to one pint of milk. There are times when eggs may be substituted with advantage for meat. This may be done on the basis of eight eggs for one pound of meat. When fruits, fresh and dried, are used in abundance, a reduction may be made in eggs, butter, cheese, and milk. While the table is intended for patients not under extra diet and attendants only, and I have suggested that 25 per cent. in the rations of meat, flour, and potatoes be added for workers, I am of the opinion that with careful management and good cooking, the supplies indicated for 100 persons for thirty days can be made to cover the entire population of most of the hospitals, including workers, patients under extra diet, and even the medical officers with their families, without deviating from the proper standard of supplies for ordinary patients."

The foregoing dietaries were in force until 1898, when there was a change in the personnel of the State Commission in Lunacy, and, on economical grounds, these were reduced. Professor W. O. Atwater was called in by the State Lunacy Commission to look into the matter. After making investigations at several of the New York State Hospitals, he stated in his report that "In providing food for the population of a hospital for the insane, two fundamental principles should be recognized. One is that kinds and amounts of food should be adapted to the actual physiological demands. The other is that these demands differ with different classes of people." Professor Atwater further says: "Regarding the actual physiological demand, as expressed in quantities of nutrients and energy of food, comparatively little is known. My own decided impression is that the principal factor is the degree of physical activity. If this is the case, the principle would be the same for the insane as for the people in normal mental condition. I am inclined to think, however, that there are exceptions to this principle; that there may be classes of the insane who eat more and may actually need more than people in normal condition with corresponding physical activity."

In December, 1900, the President of the State Lunacy Commission, having been removed by the Governor, the dietaries were again subjected to revision, and in December, 1901, were reduced and, according to the report of the State Charities Aid Association, issued recently, caused suffering and discontent to the patients. This phase of the matter, however, was treated in the Medical Record of February 21.

The question of a proper diet for the insane is a

difficult one to answer. As remarked in a former part of this article, it is generally allowed that persons suffering from mental disorders should be fed well. There is no doubt that they must not be stinted in food, or the disquiet induced by such a course will injuriously affect their mental state. On the other hand, there is no need to provide a superabundance of eatables for the inmates of State hospitals merely because they are insane, and not because it would be for their mental and physical good. It would seem reasonable that insane persons should be treated in the matter of diet in accordance with the rules dictated by those whose experience has justified them to speak with authority.

THE NURSES BILL.

An act to amend the public health law relative to the practice of nursing is now before the New York State Legislature. The object of this amendment is to prevent ill-trained or incompetent persons from posing as nurses. The act provides that the Regents of the University of the State of New York shall appoint a board of examiners, who shall judge of the fitness of candidates for registration as nurses. A candidate to be eligible for examination must be over the age of twenty-one years, of good moral character, and must hold a diploma from a training school for nurses connected with a hospital giving a course of at least two years. When these conditions have been fulfilled, and the examination passed, the successful competitors will be granted a certificate by the Regents, testifying to their qualifications to practise as registered nurses, and shall have the right to style themselves as such, which privilege will be denied to all others.

Upon recommendation of the examining board, the Regents of the University of the State of New York may, in their discretion, waive the examination of any person possessing the qualifications mentioned above who shall have been graduated before, or who are in training at the time of, the passage of this act, and who shall apply in writing for such certificate within three years after the passage of this act.

It is high time that legislation should be evoked to restrain insufficiently trained persons, from competing on equal terms with those who have passed through a curriculum which is in itself a guarantee that they possess a satisfactory knowledge of the duties that fall to a nurse's lot. Reforms have long been needed in this connection. At present the status of nurse is vague and ill-defined. There is no definite standard as to what constitutes an efficient nurse. Regulations setting forth the manner and duration of training are entirely lacking. The term "nurse," in the existing state of affairs, is so elastic that it comprehends all sorts and conditions of persons. A six months' course of theoretical instruction, or even a six weeks' course, is deemed sufficient in some parts of this country for the granting of a diploma. The consequence of this laxity is that New York is flooded with so-called trained nurses, who, attracted thither by the inducement of large wages, follow their calling, to the injury of the general public and of the really competent nurses.

Therefore, for the protection of the community at large, and of the properly graduated nurses, it is in a high degree desirable that legislation should be initiated to remedy some of these abuses and to place the whole matter on a sounder footing. This end, probably, can be reached in no better way than by placing the educational standards of the New York nurses under the control of the Regents of New York.

The New York Nurses Act is a step in the right direction, and augurs well for further and more radical reforms.

Child Labor in New York State.

Attention has been drawn somewhat sharply of late to the manner in which in some States young children are worked, and in other States, to the evasion of the laws regulating this description of labor. Ample proof has been afforded that throughout the United States the situation as regards child labor is unsatisfactory and that radical reforms are needed to remedy the evils of the present system. New York State has for many years carefully looked after the interests of its child population, and the present statutes with reference to child labor were supposed until recently to prevent its abuse. The recent agitation in the South, however, has caused the matter to be again looked into, with the result that some startling disclosures in this State have been made.

The Association of Neighborhood Workers, which was organized in New York last Spring, immediately appointed a committee to investigate the child labor situation, and the information thus collected has been published in *Charities*, January 10. Over a thousand cases have been made the subject of scrutiny, plainly demonstrating the fact that the law is constantly evaded. Factory inspectors discovered 212 children employed in factories who were under the legal age, and ninety-two who were illiterates. Testimony showing the perjury of parents was secured by the child labor investigators from many teachers of public schools in the lower grades.

According to *Charities*, one of the most striking features of the investigation has been the large number of children found entirely beyond the pale of the present law, which applies only to "factories" and "mercantile establishments." The most important among these are the newsboys, shoeblacks, peddlers, office boys, messenger and telegraph boys, and those who deliver for the express companies. It is needless to state that as a rule such a life is not conducive either to good health or to good morals. Many of these boys are ruined in both long before reaching manhood. The Association of Neighborhood Workers will, therefore, deserve well of all men if by its exertions it can prevent children from working in factories, and can hinder boys and girls of a tender age from making their home upon the streets. The proper place for children under a certain age is in school, and to school the law should compel them to go.

Physiology in the Schools.

No educational subject interests us as physicians so closely as the teaching of physiology and hygiene. Properly inculcated, these branches might do something to lessen the ignorance of the laity in matters medical. Unfortunately, as at present handled, they are about the worst-taught branches of the curriculum. The report of the U. S. Commissioner of Education for 1902 has several papers on the subject. Those by W. B. Ferguson, Superintendent of Schools, Middletown, Conn., and Prof. W. T.

Sedgwick, President of the American Society of Naturalists, trace the methods by which, since 1879, "that remarkable creation of our own times," the "temperance physiology," has been evolved into being, and has been foisted on the schools. "An Epoch of the Nineteenth Century," by Mrs. Mary H. Hunt, Superintendent of the Department of Scientific Temperance Instruction of the Woman's Christian Temperance Union, says that in New York "the campaign was systematically planned and executed. Earnest appeals from platform, press, and prayer-meeting among the constituencies back of every vote created a sentiment that echoed in the final 'aye, aye,' that enacted the law of 1884." The next step was to force the publishers into line. The Great Petition to Publishers says: "This is not a physiological but a temperance movement. In all grades below the high school this instruction should contain only physiology enough to make the hygiene of temperance and other laws of health intelligible. Temperance should be the chief and not the subordinate topic, and should occupy at least one-fourth the space of textbooks for these grades. . . . Textbooks that are largely physiology with a minimum of temperance matter . . . do not meet with the requirements of the law, and do not satisfy those who secured its enactment and are determined to secure its enforcement." Textbooks conforming to these requirements of the propaganda are "indorsed" by a "committee of the advisory board." Naturally the cupidity of the publishers prevailed, and physiology and hygiene were prostituted to a furtherance of a crusade. It has mattered not that time and again our best educators, men like Presidents Eliot and Jordan, have protested against these books by "eminent scientists," "best scientific authorities," and the "world's experts." These "eminent writers," "gifted authors," and "men of high standing and acknowledged ability," tell us that "the majority of beer drinkers die from dropsy", and that alcohol is a virulent poison, and should be classed with arsenic and mercury." "Tobacco has done more to cause insanity than spirituous liquors," "it is doing more harm in the world than rum;" "none are more likely to deceive unscrupulously than those who use the weed;" it "demoralizes; or it makes a man careless about his hair; he lets his nails go unclean," etc. It is avowed to be no part of the plan to allow this "temperance" matter to be side-tracked into a separate chapter, but every chapter is studiously rum-soaked, as the drunkard's tissues are supposed to be. "Facts" about alcohol and the bones must be learned in connection with the bones, etc.. A book of ninety pages devotes thirty-five to narcotics, and seventeen to the rest of hygiene; "foods" have four pages; the sources and nature of alcohol sixteen; "care of the brain and nerves," one page; the effect of alcohol on the nervous system, four pages; seven lines suffice to show why persons who are not growing need food, but indefinite number are required to show why they do not need alcohol.

Teaching is always by the "terrible example;" the trembling hand, thick speech, dull senses, poisoned blood, overwrought heart, weakened nerves, confused brain, foul mouth and offensive breath of the drunkard, are hysterically held up to gaze.

There is, however, such a thing as going too far. Some people can be pushed to the wall, but not through it. And the educationalists of Connecticut, in alliance with the moderate temperance element of the State, have succeeded, against the strong protest of Mrs. Hunt and her advisory board, in securing such a modification of the law as practically amounts to emasculation. The new law requires temperance instruction only from the fourth grade to, but not including, the high school, and by textbook only from the sixth grade; nothing is said as to the amount of space to be allotted, or the arrangement of the matter, and the manner of teaching the subject is left where it belongs, with the school authorities. The main significance of this departure lies in the probability of its being the first sign of a coming return to rationality, and the passing of the hysterical epoch. At any rate the attempt made in 1899 to make the Massachusetts law more rigid was a failure, owing to the strong opposition of the State Medical Society and the scientific and educational bodies, and the New York State Science Teachers' Association has recommended among other things, a modification of the State law to allow more liberty to teachers and textbook writers. Frank admission of the wide divergence of opinion among authorities should be admitted, and the chief emphasis should be placed upon the moral and economic aspects of the question. The National Educational Association, too, is bestirring itself in the same direction.

Tetanus in Gelatin.

In Bulletin No. 9 of the Hygienic Laboratory, Dr. J. F. Anderson calls attention to the several reported cases of tetanus, following the injection of gelatin as a hæmostatic and in aneurysm. His own bacteriological investigations upon six different makes of gelatin purchased in the open market, and upon the stock laboratory, gelatin led him to the following conclusions: Seven samples of gelatin examined; one showed tetanus spores. Two samples showed an oval end-spore rod, whose identity was not proved, but in stained specimens it would be hard to distinguish it from the tetanus bacillus, if indeed it be not the tetanus bacillus with diminished virulence. In tetanus investigations it is important to use *freshly* made bouillon, as the organism is apt not to germinate in bouillon over ten days old. The thermal death point of the organism isolated was found to be between twenty and thirty seconds at 100° C. It is important, therefore, that gelatin to be used for injections should be boiled at least ten minutes, on account of the variability of the thermal death point in different species of tetanus. Whether this amount of heating impairs in any way the hæmostatic power of gelatin has not been settled, but in case it does, it is believed that the danger from tetanus more than overbalances its therapeutic value. It is accordingly suggested, and with good reason, that when, as in hospitals, there is likelihood of gelatin injections being used for hæmostatic purposes the gelatin solution be sterilized by the fractional method on three successive days, and kept ready for use in sterile containers.

Sequelæ of Typhoid Fever.

At a meeting of the West London Medico-Churingical Society, held on February 6, a discussion on the above subject took place (*Lancet*, February 14). Dr. Seymour Taylor, who opened the discussion, defined sequelæ as conditions occurring after the end of the febrile process, when the temperature had been normal for two days and two nights. This speaker also mentioned in the course of his remarks, that many patients stated their health to be much improved after an attack of typhoid fever. Dr. William Hunter took a wider view of the definition of sequelæ. He regarded them as complications which occurred apart from the ordinary course of typhoid fever, and with causes different from typhoid

fever. Dr. Hunter had analyzed the cause of death in fifty cases, 48 per cent. of the patients died from perforation, 20 per cent. from pneumonia, 8 per cent. from asthenia, and 6 per cent. from heart complications, including pulmonary thrombosis, heart trombus, and fatty heart. In 10 per cent. lung troubles other than pneumonia caused death, hemorrhage in 6 per cent., and erysipelas in 2 per cent.

Dr. A. Elliot considered that, from the military point of view, the most important sequelæ of the typhoid epidemic in South Africa was disability, physical and mental. In commissioned ranks the greatest stress was on the nervous system, producing slowness of cerebration and lack of decision, often rendering the patient unfit for responsible duty in the field. Of specific sequelæ the most common and, perhaps, the most important, was phlebitis, variously estimated as occurring in from 5.6 to 25 per cent. of the cases. In epidemics in England and America the frequency was estimated at from 1.9 to 3.8 per cent.

Dr. E. A. Saunders said "that it was of great importance to separate the sequelæ due to the bacillus typhosus from those due to other microorganisms, other sequelæ might be due to staphylococci and streptococci, or to the bacillus coli. It seemed probable that many of the symptoms of severe cases of typhoid fever were attributable to simultaneous affection with the bacillus coli communis."

There are some points of interest in the above discussion. Probably, as Drs. Hunter and Saunders said, complications accurred after typhoid fever, which are generally regarded as sequelæ, but which, in truth, cannot be directly attributed to the fever. Of course this view depends, to a great extent, as to how sequelæ are defined. The large number of cases of phlebitis following an attack of typhoid fever, which occurred among the British troops in Africa, is another point worthy of notice. Many theories have been advanced to account for this coincidence, none of which, however, appear to explain the circumstance satisfactorily.

The Medical Department of the Army Transport Service.

In the *Journal of the Association of Military Surgeons* for January, 1903, Maj. H. S. Kilbourne describes, with special reference to the Medical Department, the growth of the Transport Service from its inception under the stress of war (in which stage it was notoriously disgraceful, and of which the author diplomatically says: "The condition of the victorious troops on landing at Montauk, at the close of the campaign, is too well known to need comment") to its present developed state. The Transport Service now forms a separate branch of the Quartermaster-General's Department, with headquarters at New York and San Francisco. Summarizing the experience acquired, it has been found that soldiers, and especially unseasoned troops, require different treatment from sailors. Unaccustomed to the sea and to the monotony of ship life, soldiers quickly fall out of condition for service unless special care be taken. A constant tendency toward overcrowding, general seasickness, and the prevalence of the infectious diseases, render effective sanitation difficult. Greater obstacles arise from the necessary economy of space. The prevalent dampness of the lower decks was diminished by incast and extraction fans. Free circulation below is a prime necessity for vessels in the tropics, where combined heat and humidity are inimical to passengers and cargo. Apparatus for cooling or warming the distributed air added further to health and comfort. Folding messroom furniture admitted of the clearing of the deck for exercise and recreation during heavy weather. The refrigerating apparatus improved the dietary by affording opportunity for cold storage and also ice for the sick. The segregation of the sick with adequate hospital appliances, facilitated their proper care and the protection of the healthy. Lavatories, baths, latrines, and a laundry were installed on the troop decks. An ample water supply was secured by the double system of storage and distillation. Separate galleys for soldiers' mess, at which a full ration could be prepared, were installed, and strict cleanliness on the berth decks, two in number below the main deck, was enforced. On the berth decks 78 cubic feet per man was deemed sufficient in view of the fan ventilation, electric lighting, and cleanliness of the person, bedding, and decks. For disciplined troops a wash basin for each ten men, a closet for twenty, and a shower bath and urinal for thirty, are sufficient. During the day the men live on the upper decks. From one-third to one-half the men can be served without delay at the mess. On the larger transports the hospital occupied the after main deck and accommodated from 3 to 5 per cent. of the troops, with an air space per man of 100-150 cubic feet, in the main ward. Above the latter an isolation ward, with a separate room for intractable patients, could accommodate 6 to 12 per cent. Separate lavatories, baths, and closets for this ward secured isolation of infectious cases. A lavatory, closets, a dispensary, operating room, a linen room, special diet kitchen, surgeon's room, and rooms for attendants, all with requisite furniture and fixtures adjoined the main ward. A general medical storeroom opened from below through the floor of the main ward. Air ducts overhead, having lateral discharge into the ward, supplied adequate ventilation in heavy weather. Double tier steel berth sections, with woven-wire beds, later exchanged for canvas, were secured to the deck. Instruments, and three months' medical supplies, completed the equipment. The bed supply proved adequate except when measles war epidemic. Quarters for female nurses were omitted as inexpedient in transport hospitals. When passengers on board their services have often been utilized and proved valuable.

More "Bloodless" Surgery.—The newspapers herald, with many details as to opposing religious beliefs yet commendable charity and toleration, the proposed return to this country of Dr. Lorenz's assistant. Although he is a Roman Catholic, the innocent reporters say, he has nevertheless agreed to operate (bloodlessly of course) "free of charge upon all poor Jewish cripples who may present themselves during his sojourn in this city." This wonderful exhibition of Christian charity, the papers add (in nearly identical language), "is simply a special favor to Dr. Singer, who is his friend and countryman and a former pupil of his father, late professor of comparative philology at the Vienna University. Neither the Beth Israel Hospital, which is open to all, regardless of color and creed, nor Dr. Müller, nor Dr. Singer has the slightest desire or intention to deprive anyone afflicted of the benefits of the Lorenz method." We had hoped that orthopedic surgery, not to mention orthopedic surgeons, in this country would have been content with the publicity enjoyed during Lorenz's royal progress—but it seems not.

News of the Week.

The Typhoid Epidemic at Ithaca.—The State Board of Health has been investigating the cause of the outbreak of typhoid fever at Ithaca, and the means of preventing a recurrence. The recently issued bulletin of the Board says that "by what means either of the three small streams furnishing the water supply became infected thus to produce this abrupt, unseasonable outbreak has not been determined to full satisfaction, but, of unusual conditions, there was emptied upon the ravine-like banks of one a body of foreign laborers during the fall and early winter building a dam, who departed with advent of frost. Among them were probably carriers of typhoid germs, which the first soft weather carried into the stream. A bill has been introduced into the Legislature providing for the prevention of pollution of all streams in the State. The measure will give authority to the Health Commissioner to force all municipalities and employees of large bodies of men to dispose of all refuse matter and sewage in such a way as to render the pollution of water supplies impossible. It is estimated that there have been over 500 cases of typhoid fever at Ithaca, but the number of new cases is rapidly decreasing, and it is believed that the epidemic is practically at an end.

A Strike of Hospital Nurses.—Nine trained nurses at the New York Eye and Ear Infirmary left the hospital at a few hours' notice some days ago, abandoning fifty-seven patients to be attended to by the head nurse and an assistant. So far as can be learned from the accounts given, the nurses objected to the presence of one of their number who wore a white dress. The chief surgeon of the infirmary promptly secured a new nursing staff, and the ladies who retired are looking for another job.

The Work at Stony Wold.—The work contemplated by the Stony Wold Sanatorium for Women and Young Children is explained, and the fact that tuberculosis is curable and preventable is emphasized in an appeal made on behalf of the institution by Mrs. James Edward Newcomb, President of the Board of Directors. The sanatorium is at Lake Kushaqua, 1,200 acres having been purchased for $20,000. A central building and one dormitory are approaching completion, and the foundation for a second dormitory has been finished. To complete the work about $60,000 is needed. For the entire equipment of the institution $200,000 is to be required. The present plan of the directors is to open the sanatorium in August next.

A Cruel Blow to Healers.—A bill has been passed by the State Senate of Virginia forbidding Christian Scientists to practise their profession of healing the sick in this State and charging therefor, unless they have been duly examined and licensed by the State Board of Stated Medical Examiners. These practitioners will have to content themselves hereafter with a shadow of a fee as unsubstantial as the thought of disease which they claim to dispel.

Running Amuck with Dental Forceps.—A crazy dentist in Duluth dreamed he had a mission to extract the molars of the multitude. He started out early in the morning and began his mission by pulling the teeth of four men who were found intoxicated in a saloon. A little while after that he accosted an old man on the street, knocked him down, and pulled two teeth. A few minutes later he entered a house, and finding a woman preparing the breakfast, knocked her down and extracted two teeth. Then he fell into the hands of the police.

A Peripatetic University.—The country medical practitioner in Germany is to have an opportunity to learn the latest developments in surgery and general medicine from a travelling university that will bring post-graduate instruction to the nearest large town in his vicinity free of charge. The scheme has received the approval of the Emperor, and will soon be put in execution. The expense of the undertaking will be met by the government.

Formalin Injections in Rabies.—A patient in the Williamsport, Pa., Hospital, suffering from rabies, is reported to have been cured by intravenous injections of formalin solution. His arm had been mangled by a mad dog, and was amputated, but rabies developed later. A rapid fall of temperature and improvement in all the symptoms is said to have followed the administration of the remedy.

Famine in Japan.—It is reported that a practically complete failure of the rice crop last year has caused widespread distress in Japan, culminating in famine in the Northeastern provinces. The number of destitute, so far as officially known, is 147,700.

Defeat for the Osteopaths in Alabama.—Dr. Robert N. Pitts, Health Officer of Montgomery county, Ala., writes that a bill granting many privileges to the sect of osteopaths, which was under consideration in the present session of the Alabama Legislature, was defeated after a long and hard-fought battle. If the bill had passed it would have practically nullified the present well-nigh perfect medical laws in that State, and would have materially lowered the existing medical standard. The champion of this bill was a woman who practises osteopathy in Mobile, a licensed practitioner in Alabama, having passed the required examination before the State Board. The bone squeezers had an array of some of the best legal talent in the State lobbying for the bill. If the bill had passed, all of the osteopaths who had practised in the State before the 1st of January, 1903, would have been legalized practitioners by the act. The bill provides for an osteopath on the State Board, and these persons would have had three-tenths of the branches to propound questions on and rate the answers, including gynecology, obstetrics, toxicology, and the practice and principles of osteopathy. We congratulate Alabama on her escape.

College of Physicians of Philadelphia.—At a stated meeting, held March 4, Dr. Francis R. Packard read "A Memoir of the Late Dr. Charles H. Burnett," Dr. William G. Spiller presented a communication entitled "A Physiological, Anatomical, and Pathological Study of the Glossopharyngeus and Vagus Nerves in a Case of Fracture of the Base of the Skull." The most conspicuous symptom was difficulty in swallowing. The pharyngeal reflex was preserved, as was also the sense of taste on the anterior portion of the tongue. After death the vagus and the glossopharyngeus were found disorganized on one side, the lungs the seat of multiple abscesses, and liver and kidneys degenerated. Dr. Charles H. Frazier read a paper entitled "A case of Unilateral Pulsating Exophthalmos; Ligation of the Right Common Carotid and Left Internal Carotid Arteries; Recovery," and he exhibited the patient, who was a young man who had been shot in the right mastoid region. Exophthalmos, with noises in the head and a bruit demonstrable objectively developed, and the operations indicated were performed to secure relief. The first yielded no satisfactory result. Following the second, there was after a time some amelioration of the symptoms,

but the most marked improvement followed a collision with another person. Drs. M. Howard Fussell and Henry D. Jump reported a case of probable multiple serositis, and exhibited the patient, a young colored man, who had presented symptoms of pericarditis and of enlargement of the liver with pulsation. There was a history of pleurisy, and there was also impairment of resonance over the upper portion of one lung and œdema, but no ascites. Announcement was made that $53,000 had been subscribed to the building fund to meet the proffer made by Mr. Andrew Carnegie of a gift of $50,000 on condition that a like sum be raised by the college, and that a communication had been received from Mr. Carnegie stating that a check for the amount named would be forwarded.

Department of Physical Education at Columbia.—The work in physical education at Columbia University is to be unified and brought under the administration of one department, of which Prof. Thomas D. Wood is to be the head, with a seat in the faculty of Teachers' College. The equipment of the department will consist not only of the university gymnasium, but of the new building now being erected by Teachers' College solely for physical education, the funds for which were given by Mrs. Frederick F. Thompson. The university gymnasium will be in charge, after July 1, of Dr. George L. Meylan of Boston as adjunct professor of physical education.

The Columbus Hospital, New York.—Dr. G. A. DeSantos Saxe has been appointed assistant pathologist to this hospital. The institution is to be enlarged shortly by the addition of new buildings, the ground for which, adjoining the present property, has already been purchased. The erection of these new buildings will increase the capacity of the hospital to 150 beds, instead of the present 98 beds. Funds for the erection of the buildings are available, which will be sufficient to provide for a modern equipment of the new wards.

The Missouri State Medical Association.—The date of annual meeting of this society has been changed from May 19, 20, and 21, to April 21, 22, and 23. The place of meeting remains unchanged, Excelsior Springs. Further information relating to the meeting may be obtained from the secretary, Dr. C. M. Nicholson, 2900 Washington Avenue, St. Louis.

New York Polyclinic Medical School and Hospital.—At a recent meeting of the faculty of this institution Dr. Charles Gilmore Kerley was elected professor of pediatrics, and Dr. J. A. Bodine professor of surgery.

Dr. D. S. D. Jessup, one of the teaching staff in the College of Physicians and Surgeons, has been appointed to the recently created office of medical visitor to Columbia University in this city.

Brain Vision.—A writer in a recent number of the Paris *Revue des Revues* describes an appliance invented by a Dr. Steins; by means of which it is claimed that the blind, if their loss of sight is the result of ocular lesion, can be made to see. The writer says that the apparatus was applied to his temples while he was blindfolded, and affirms that it enabled him to see. In this age it is unwise to deny the possibility of anything, but neither is it wise to accept unsubstantiated tales as facts, and this is certainly wildly improbable.

The Plague at Mazatlan.—There were fifty deaths from the plague at Mazatlan during February. Between January 15 and February 28 inclusive 291 houses were burned. Isolated cases of the disease are reported from various towns along the west coast of Mexico, but all danger of an epidemic appears to have been averted by the energetic action of the Mexican health officials.

Psychiatrical Society of New York.—A society with this name has recently been organized. Its object is to promote the interests of psychiatry and to stimulate its study. Active membership is limited to fifteen. The meetings, which are held on the first Wednesday of November, January, March, and May, are at the houses of members. Officers: Dr. Allan McLane Hamilton, President; Dr. Frederick Peterson, Vice-President; and Dr. Pearce Bailey, 52 West Fifty-third street, Secretary.

Silkworm Gut for Sustaining Sutures in Fixation of the Kidney.—Dr. Augustin H. Goelet writes: On page 398 of your issue of March 7, in the report of the proceedings of the New York County Medical Association, it is incorrectly stated that I prefer silk for suturing the kidney. I employ temporary sutures of silkworm gut, which are brought out through all the structures of the back and tied over a fold of gauze.

Trouble at a Hospital in Richmond Borough.—The Richmond County Medical Society at its February monthly meeting adopted resolutions requesting the Board of Trustees of the S. R. Smith Infirmary, the only public hospital in the Borough of Richmond, to remove the superintendent of that institution, against whom complaints have been made from time to time. The superintendent, Miss Twitchell, has been at the head of the institution for nine years, and in that time there have been several attempts to displace her, but without any success. During her administration she has at times been highly praised by some for her work, and also as severely criticised by others.

The Death of Dr. T. Gaillard Thomas.—On motion, the following resolution was adopted by the Medical Board of the Woman's Hospital, State of New York, at its meeting held on the 5th of March, 1903; and it was voted that a copy of the same be sent to the Board of Governors, and that it be published in the MEDICAL RECORD and the *American Journal of Obstetrics*, and that a copy, suitably engrossed, be forwarded to the family of Dr. Thomas:

Resolved, That we record with feelings of the deepest sorrow the death of our associate, Dr. T. Gaillard Thomas, President of the Medical Board and a Consulting Surgeon to the Woman's Hospital, which took place at Thomasville, Ga., on February 28, 1903.

Dr. Thomas devoted the best years of his professional life, from 1872 to 1887, to the service of this hospital as an attending surgeon. During all these years his ability as a diagnostician and his brilliancy as an operator were the admiration of his colleagues. The results of his scientific work added largely to the reputation of the hospital and greatly broadened the sphere of its usefulness. He merited, and easily won, the confidence of his patients; they trusted him as friend as well as surgeon. His assistants and the members of the house staff found him always most kind and considerate; he would oftentimes spare them, but never himself, when unusually laborious work was to be done. He was honorable, unselfish, a noble man, whose precept and whose example alike inspired many a young colleague to strive after the highest ideals that can be set before a physician.

Full of years and of the honors that had been conferred upon him, happy in the affection of his friends, his life work completed, at peace with God and with his fellowmen, he has gone to his reward.

Committee.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

HOSPITALS: THE HERBERT, OPHTHALMIC, BART'S, CHARING CROSS—HUNTERIAN ORATION—EARL ROBERTS, F.R.C.S.—LEAD IN MOORLAND WATERS—VICTORIA UNIVERSITY—"TUBE" ATMOSPHERE—A NURSING PROBLEM—CORONERS.

LONDON, February 20, 1903.

THE King and Queen went to Woolwich on Monday on a visit of some importance to the Herbert Hospital—the great military hospital named after Sidney Herbert, who was war minister during the Crimean War, and was stimulated by the sufferings of the troops to attempt by this and other means to alleviate them as much as possible. The Royal Family has always taken special interest in this hospital. Queen Victoria visited it in 1900, within a year of her death, when the South-African War put a heavy strain on its resources, for during that struggle upward of 10,000 wounded and sick soldiers passed through it. There are now about 550 patients in the wards. The immediate occasion of the royal visit this week was to inaugurate the rearrangement of the nursing staff consequent on the introduction of Queen Alexandria's Imperial Nursing Service, which now takes the place of the former Home and Indian nursing staffs. The new quarters for the nurses were inspected by their Majesties, and were pronounced satisfactory. The Queen distributed medals in gold, silver, and bronze to nurses on the staff, and a visit was afterward paid to some of the wards. Some of the patients seemed much cheered by the kindly words of their royal visitors. Finally, the King presented South-African medals to twenty-seven men now attached to the hospital, who had done service during the war, and the Queen expressed her satisfaction at the way in which her Imperial Service had been organized in the Herbert Hospital.

While the King and Queen were visiting the Herbert Hospital, the Lord Mayor and Lady Mayoress were visiting another—that was the Royal Ophthalmic. The object of this was to open formally thirty additional beds. This hospital, so long known as Moorfields from the locality it occupied, was founded in 1804, and has always been supported by the city magnates. It was regarded as the mecca of ophthalmology. The removal from the old site where it was almost rent free, for a new locality, with a heavy ground rent, and rated at £1,000 a year, provoked a good deal of criticism, which the vice-chairman endeavored to meet in proposing a vote of thanks to the Lord Mayor. He said that rebuilding was necessary; he sold the old site for £78,500, and they had paid the last bill for the new hospital. But he naturally protested against the exorbitant rates exacted. The Lord Mayor remarked that if no favor was shown to hospitals by rating authorities, they ought to contribute to their support.

The Committee on St. Bartholomew's Hospital has held three sittings, and meets again this afternoon to consider the question of removal from or retention on the present site.

The annual meeting of Charing Cross Hospital was held on Wednesday when some figures were presented which provoke serious thought. The excess of expenditure over receipts reached £22,385, and the year began with a deficit of £14,000. The extraordinary expenditure amounted to £33,000, and it was stated that £62,000 would be required for the current year. The annual subscriptions reached £2,411, and yet all the year building has been going on. No wonder that while managers are making urgent appeals for money, doubts are freely expressed as to their capacity, and many medical reformers are quoting the extravagance as an argument that this hospital is not required in the position it occupies.

On Saturday the Hunterian Oration at the Royal College of Surgeons was delivered by Sir Henry G. Howse, president. The orator gave a sketch of the career of John Hunter—an oft-told tale, but ever interesting. He was throughout a genuine collector, as well as one of the most admirable experimenters. He spent £70,000 on his museum, which on his death was the only thing he left to his widow. Six years later it was purchased for £15,000, and in 1804 the government advanced £27,500 to accommodate the collection. Since then it has been enlarged four-fold by the college—the trustees of the nation. Sir H. Howse thought that Hunter had a prevision of the Darwinian theory, in support of which he exhibited some fossils of animals from which it was supposed the horse descended, and described the gradual structural changes which were conjectured to have taken place. The orator concluded with sympathetic references to the death of two members of the council, Mr. Spencer Smith and Sir William MacCormac.

In the evening the annual dinner was held at the college, the president in the chair. The guest of the evening was Earl Roberts, who received the Honorary Fellowship of the college. The loyal toasts were first duly honored, and the memory of John Hunter drunk in silence. Then the president proposed the guest of the evening, remarking that two years ago, on the occasion of the centenary of the college, the Honorary Fellowship was instituted. The first to accept it was the King, then Prince of Wales; the second, Lord Roseberry, and now he asked Lord Roberts to accept it, and sign the roll. No man had done more for the medical department of the Army, and no one better earned the honor of the college.

Earl Roberts made one of his effective speeches accepting the fellowship. He said it was quite two years since the late Sir Wm. MacCormac wrote to ask him to accept the honor which the college offered. But while the war was going on, he was not inclined to accept any honors or rewards. Now all was changed, and he was delighted to be present. He accepted the honor on behalf of the navy, army, and auxiliary forces to whom he owed everything. It was equally true that all three owed a great deal to the Army Medical Corps. Only those who had been in South Africa could appreciate the devotion of the officers and men of that corps or the admirable way they mastered difficulties. The way they met and conquered these difficulties excited his highest admiration, and he did not forget, nor was he likely to forget the support rendered to the army medical service by their professional brethren, who went out to help them in the field. He mentioned Sir W. MacCormac, Sir. W. Stokes, and many survivors. Though, as the president had told him, the Honorary Fellowship did not give him the right to use the scalpel or the forceps, he would always, in all circumstances, do all he could to help the sick and wounded.

Mr. W. H. Power, medical officer of the Local Government Board, has this week issued a report on lead poisoning by water derived from Moorland sources. It contains the results of a survey by Dr. Houston, of fifty-eight reservoirs, in thirty-five of which the water could take up lead. In many this was traced to peaty sources, which frequently possess an action on lead. Filtration through sand seems to neutralize this action. Dr. Houston says it is not only necessary to test reservoirs and main streams, but the tributaries and subsidiary feeders during different seasons of the year and under ordinary and extraordinary conditions of rainfall.

The disruption of Victoria University is decided on. Founded in 1880, it comprised Owen's College, Manchester, and other colleges in Liverpool and Leeds. Liverpool wanted a university all to herself, and the question of granting it has been argued before the Privy Council, of which the committee has decided, with approval of the King, in favor of separation. But before giving practical effect to this decision, the committee desires the Leeds College to have the opportunity of submitting a draft charter for the incorporation of a university for Yorkshire, and also the three institutions are to consider in detail points on which joint action is desirable, and how that can be secured without restricting the liberty of each. How far increasing the number of universities will be beneficial remains to be seen.

The atmosphere of the "Tube" railway has been much talked of, and on Wednesday the County Council had before it a report of its Public Health Committee. This stated that the amount of carbonic acid was high in the carriages, but curiously enough the greatest quantity was not in the smoking compartments. Samples taken at midnight and in the early morning were fair. About 66 per cent. of the samples contained two and one-half times as much as the outside air. Dr. Andrews considered twice as much ought not to be exceeded. Microorganisms were present in some excess of the outside air, but not greater than in inhabited rooms generally.

When is a nurse not a nurse? Answer—when she is "qualified." I am indebted for this reply to a committee appointed by the Local Government Board in January, 1902, of which the report has just appeared. There was some difficulty experienced at times in procuring poor-law nurses in emergencies. The term "trained nurse" is always understood to mean one who has had three years' training. This report proposes an inferior order of one year's training in the smaller work-houses, and these inferior ones are to be called, in order to distinguish them, "qualified nurses," and are to be recognized as fit to fill any post in the nursing service of the poor-law system. Farther, they are to get certificates of training. So the country may be flooded with a number of women certified as "qualified." It is only to be expected that they will leave the work-house service and seek employment with the public. They will exhibit their diplomas as "qualified nurses" and be ready to undertake all sorts of practice.

Thus, the diploma traffic of the Obstetrical Society will be outdone by that of the Government Board.

Mr. Coroner Troutbeck persists in his folly, and, as I predicted, we are learning something more about autopsies. I feared there might be something in the statement that busy practitioners were tempted to perform post-mortems in a rather perfunctory manner. Now it appears that a professed pathologist may run the risk of a similar charge. At an inquest the other day the one employed by Mr. Troutbeck had to admit he had employed the porter to open the body, as he suffered from sore hands, and he talked of having done so in thousands of cases. It seemed he did not touch any of the viscera, though he stated their condition!

Another coroner has been exposing his office to contempt—saying if a doctor "cannot tell anything without cutting up a body and annoying the relatives and the whole street" he would do without him, if possible. Other equally silly remarks show that this gentleman is unfit for his office, and I should like to see his conduct laid before the Lord Chancellor.

THE WORK OF THE FRESH-AIR SOCIETY.

To the Editor of the Medical Record:

Sir: During several summers past I have inspected the vacation parties which the New York Association for Improving the Condition of the Poor have sent down to Sea Breeze, their establishment on Coney Island. The main purpose of these inspections has been to exclude cases of infectious disease. During the last summer but one such case developed—a case of whooping cough.

I observed last summer that some untoward conditions existed, as in other years; but they appeared to me to be considerably mitigated. The number of unvaccinated children was certainly much less than in other years; and these unvaccinated were most of them infants of but a few months. I only occasionally came upon cases of pediculosis, molluscum contagiosum, and like affections, born of uncleanliness. Infants were not so dreadfully overclothed; still at every examination there were instances of this species of torture. There were also constantly appearing instances of illness due to over-feeding or irregular feeding; but this condition of things will obtain, I suppose, so long as children have appetites, and mothers are tender and solicitous. As before, mothers comparatively young appeared with large families—up to nine children. Of these mothers not a few were haggard and careworn; several were consumptive.

Cases of "running ear," sometimes accompanied by the dreadful odor of necrosis—were not infrequent. There were far too many cases of adenoids and hypertrophied tonsils. These children, mouth breathers, with unexpanded lungs, contracted chests, pinched alæ, and sallow faces, presented quite ideal conditions for the reception and maintenance of the tubercle bacillus.

I came upon not a few babies who had been at the breast for from sixteen months to two years or longer. The reasons why mothers continue this lactation, and its baneful sequelæ, are known to medical men.

I have each year observed among these children a large proportion of cases of granular lids. Last summer I found some 10 per cent. affected, somewhat fewer than in former years. It is a matter of great satisfaction to note in this connection the work which the New York Health Board is doing. Its examiners are finding from 10 to 20 per cent. of the children in the public schools to be afflicted with granular affection. For instance, in one class of about sixty, on the lower East Side, an examiner found twenty-three such cases. Most of these children are of immigrant parentage from Europe—people who have come over in the steerage. The disease, indeed, must be much more rife in Europe than among our native population, as one may satisfy himself who would inspect the steerage contingent of any German or Dutch ship coming to our port.

Among isolated cases which had for me a somewhat gruesome interest, the following might be noted:

A girl in her teens, blind since three days after birth—a case of ophthalmia neonatorum; another with an immense goiter, the exophthalmos and the tachycardia being also very manifest; an idiotic child, who became so after recovery from cerebrospinal meningitis (such recoveries, attended as they are with such sequelæ are hardly to be wished for); a child with facial paralysis, which followed upon a button having remained for a long period in her nostril; a woman who alone supported her husband and family, because he had an aneurysm, which must inevitably prove fatal; an infant, with an enormous hydrocephalus, certainly larger than an adult's head; a girl of eighteen, who had already undergone an operation, and was joining the party in order to become strong enough for another on her return to the city; a mother in the same circumstances (these cases are not infrequent); a woman with hysterical deafness (unfortunately unaccompanied by aphonia), which, she declared, came upon her in an instant, and which is likely to leave her as suddenly; an imbecile boy; choreic children; cases of Pott's disease of the spine; syphilitic infants, whose fathers had had "blood poisoning"; women with heart and kidney lesions written upon their faces; a child who was a cretin; a woman whose left side had been burned, the cicatricial tissue being so tense that she had to remain erect, and could not bend over—and so on, a panorama gruesome enough, as our friend Thomas Carlyle might have said. Year before last there was an optimistic and most genial, light-hearted mother of nine children. I had asked her was she well. "Sure," she had answered, with a grin and a twinkle of the eye; "only for that I couldn't stand the racket." Since then this woman has died of consumption.

I think most medical men comprehend how greatly charity—especially medical charity—is overdone in this city, and how baneful are the influences attending this superzealousness upon our poorer classes. It is, however, a matter of gratification to observe that the work accomplished by this association is beneficent quite without qualification. It concerns itself—so far as these vacations go—not at all with men. Only worn-out women and sickly children get this outing. Women who are tired both in mind and body; widows, or those whose husbands are worse than dead; women who have many children in their families; who have chronic affections of various organs; many old women, too; and infants and children in hot and crowded tenements; all these have their lives prolonged through the activity of this excellent organization.

It is worthy of reflection that lack of education and uncleanliness are the two factors most responsible for the untoward conditions noted in this letter. Descartes was not altogether right when he declared that if the race is ever to attain perfection it must be by means of the medical sciences. However, if the principles of prophylaxis and sanitation were universally grasped and applied, the race would certainly be far advanced toward an ideal state.

John B. Huber, A.M., M.D.

44 East Sixty-fourth Street, New York City, January 27, 1903.

PROPHYLAXIS OF VENEREAL DISEASES.

To the Editor of the Medical Record:

Sir: At the last (fifty-third) meeting of the American Medical Association, held at Saratoga Springs, June 10-13, 1902, a joint resolution from the Sections of Cutaneous Medicine and Surgery and Hygiene and Sanitary Science was introduced in the House of Delegates as follows:

"*Whereas*, There is a burning necessity to check the spread of venereal diseases, and, assuming that the States cannot, with impunity, ignore the condition, it lies in the province of the medical profession to discuss and recommend to the respective State legislatures and municipalities means not regulamentative, but social, economic, educative, and sanitary in their character, to diminish the danger from venereal diseases.

"*Resolved*, That the Section on Cutaneous Medicine and Surgery of the American Medical Association invite the section on Hygiene and Sanitary Science to coöperate with the Section on Cutaneous Medicine and Surgery in bringing about a propaganda in the different States, looking toward a proper recognition of the dangers from venereal diseases, and to arrange for a national meeting under the auspices of the American Medical Association for the prophylaxis of venereal diseases, similar to the International Conference for the Prophylaxis of Venereal Diseases, which meets again this year at Brussels, under the authority of the Belgian Government."

This was later submitted to the House of Delegates, which endorsed the action of section and adopted the following:

"*Resolved*, That a joint committee of six from the sections on Hygiene and Sanitary Science and Cutaneous Medicine and Surgery be appointed by the President to stimulate study in and uniform knowledge of the subject of the prophylaxis of venereal diseases, and to present to the American Medical Association a plan for a national meeting similar to the International Conference for the Prophylaxis of Venereal Diseases, which meets again this year in Brussels, under the auspices of the Government of Belgium."

The Committee on Prophylaxis of Venereal Diseases consists of Dr. Henry D. Holton, Chairman, Brattleboro, Vt.; Dr. Ludwig Weiss, Secretary, 77 East Ninety-first street, New York; Dr. George M. Kober, 1600 "T" street, Washington, D. C.; Dr. W. H. Sanders, Montgomery, Ala.; Dr. L. Duncan Bulkley, 531 Madison avenue, New York

City, and Dr. Frank H. Montgomery, 100 State street, Chicago, Ill.

The peculiar social, racial, and political conditions of our country are so different from those on the Continent that they necessitate an expression of solely American ideas on this mooted question, both from a socio-economic and sanitary point of view.

The Committee desires the support of the medical profession, and the aid and powerful collaboration of the medical press of the country to help it in this work. It takes the liberty of soliciting expressions and views editorially and otherwise, and would be glad of personal correspondence from those supporting the movement, and who will contribute by papers, etc., to make it a success in case the House of Delegates should favor the holding of such a Congress.

By giving this a place in your esteemed paper, the Committee feels that you will have aided materially in forwarding the work entrusted to it.

Ludwig Weiss, M.D.,
Secretary of Committee.

Progress of Medical Science.

Boston Medical and Surgical Journal, March 5, 1903.

Cytodiagnosis: A Study of the Cellular Elements in Serous Effusions; a Preliminary Report.—Percy Musgrave reports six cases in which a cytodiagnosis was made. He states without hesitation that the descriptions given by Widal and other observers have been accurate, so far as his limited observation has gone; not only from observations made on the reported cases, but from several preparations made from abdominal fluids. The writer believes that this procedure will be found of clinical value after a more thorough observation and study. If it is found that the cytological formulæ are accurate after careful control of the cases studied, it is plain that the immediate results which can be obtained by this method, and which the French observers claim are more accurate than any clinical method now practised, will be of much value in diagnosis as well as prognosis.

A Research into the Means of Controlling the Blood-pressure.—George Crile says that in many instances the control of the blood-pressure is synonymous with the control of life itself. Saline infusion in shock has a limited range of usefulness. In collapse it may be effective. The blood tolerates but a limited dilution with saline solution. Saline infusion in shock raises but cannot sustain the blood-pressure. Adrenalin acts upon the heart and blood vessels. It raises the blood-pressure in the normal animal; in every degree of shock; when the medulla is cocainized, and in the decapitated animal. It is rapidly oxidized by the solid tissue and by the blood; its effects are fleeting; it should be given continuously. The pneumatic rubber suit provides an artificial peripheral resistance without injurious side effects, and gives a control over the blood-pressure within a range of from 25 to 60 mm. mercury. By the combined use of artificial respiration, rhythmic pressure upon the thorax, and adrenalin injected into the jugular vein, animals which were apparently dead as long as fifteen minutes were resuscitated.

Symptoms Simulating Appendicitis Caused by an Intra-abdominal Band.—James A. Keown reports the case of a boy of eight years, who for two years had suffered more or less distress in the abdomen in the vicinity of the umbilicus. After a long period of freedom from pain he was suddenly seized with vomiting, pain in the abdomen, and marked tenderness at the umbilicus and over McBurney's point, with rigidity. The temperature rose to 102° on the second day and slowly subsided during the next week. The patient was seen by another physician who diagnosed the case as appendicitis. The mother became alarmed, and as the existence of appendicitis could not be ruled out, the patient was operated upon. The appendix, except for the fact that it was six inches long, was found to be normal. On more careful examination for the source of the pain, a band was found running from a loop of small intestine upward to the umbilicus. This was ligated and removed; the stumps were turned inward, covered by peritoneum. This, on examination, was found to leave an opening part way on the bowel side. At about the end in connection with the bowel, the peritoneum was granular and red. The abdomen was closed, and the patient made an uneventful recovery.

Journal of the American Medical Association, March 7, 1903.

Fevers of Doubtful Nature in Infancy.—Basing his statements on his personal experience in Cuba, J. L. Duenas expresses his belief in the fact that many of the summer fevers in Havana, generally regarded as either malarial or attenuated forms of typhoid are in reality of gastro-intestinal origin, and advances the following reasons for his belief: (1) "Etiologic investigation always reveals more or less transgression of dietetic hygiene, as shown by abnormal discharges. (2) Epidemiologic investigation shows, on the other hand, that the disease is more frequent during the warm weather and coincides with the development of fever of typhic nature, with the different types and varieties of gastrointestinal accidents, in many children under two years of age, and with the remittent prolonged cases of fever in children above that age. Its frequent repetition observed in the same child, and always obeying to the same cause, dissipates all ideas of typhoid or yellow fever; diseases which do not attack the same person twice in accordance with the opinion generally established and admitted. (3) The bacteriologic examination demonstrates the existence of great number of bacillus coli communis in virulent condition, as well as of other saprophites in the potable waters of Havana. Very frequently unboiled water is administered to nursing children. (4) The hematologic examination reveals the absence of plasmodies in the blood obtained from these small patients as well as the absence of the serum reaction of Widal. (5) Quinine, even given hypodermically, is useless unless intestinal elimination is previously established.

The Identity of Nerve Force and Electricity.—J. E. O'Brien summarizes his study of this subject by calling attention to the fact that the construction of nerves has been closely though unconsciously imitated in electric cables, and contends that experiments on nerves should be interpreted according to the electrical peculiarities of cables, and not as if they were bare conductors. Nerves are insulated, distributed, and arranged like fine electric conductors. Their purpose and use are the same as the purpose and use of electric conductors, namely, communication from point to point. They convey some form of force, and there is not such a gulf between its velocity and that of electricity as has been supposed. This force must be electricity because: (1) Electricity is always present when nerves act. (2) Electricity is the form of force that would do the work required. It is the form of force that would work with such construction. (3) Because the terminal and central mechanisms connected with the nerves correspond to the terminal and central mechanisms connected with electric systems of communication and do similar work in sending, receiving, relaying, switching, transforming, accumulating, retarding distributing, and translating impressions. (4) Finally because electricity, with such construction of conductors and of terminal mechanisms is the only form of force that we know of that would do all the work required. He therefore maintains that nerve force is electricity, and that it would advance knowledge of the nervous system and its functions to accept this proposition.

Mercury in Syphilis.—Eugene Fuller advises careful attention to the teeth and gums during the administration of mercury. The toothbrush should be used thoroughly, and the mouth rinsed twice daily with peroxide. If the patient bears the remedy easily, well and good; if not, we may use the fumigation and inunction methods. If an individual presents himself during the primary stage of syphilis and keeps under observation so that mercurial treatment can be inaugurated as soon as a definite diagnosis can be made, we should begin with mouth administration. If the drug so administered is satisfactorily tolerated, and succeeds in not only dissipating the symptoms which may be present, but also in preventing the development of new ones, then there is no good reason for displacing the method first adopted in favor of another. Not infrequently in such an instance, however, mercury by mouth, although well tolerated, may not, especially during the first few months of its administration, be potent enough to hold the disease entirely in abeyance. In such cases a hypodermic injection given from time to time will satisfactorily supplement the effect of the mercury taken by mouth. If a person presents himself for the first time late in the secondary stage of the disease, where, owing to anæmia, facial or other prominent eruptive manifestations, alopecia, cephalalgia, rheumatoid pains, mucous patches or like developments, it may be of the greatest importance to quell symptoms quickly, not only for the good of the individual, but also to prevent the fact that syphilis has been contracted from becoming generally known; then hypodermic medication is to be recommended, owing to the quickness of the ensuing results, a marked fading in connection with an eruptive lesion and decided cessation in connection with pain being noted even after the first injection. In a case such as this after the disease is well under control, then it may be that another form of medication can be substituted.

Medical News, February 28, 1903.

Thyroid Extract in Hæmophilia and Other Forms of Hemorrhage.—Eugene Fuller reports a case of hæmophilia in a boy of fifteen years, which resisted all treatment till thyroid extract was administered, five grains three times a day After the second dose all bleeding stopped. The improvement in his general condition was marked. In the case of another patient, a man fifty-five years old, this same drug was productive of brilliant results. The patient had been suffering from nephritis for some time, and a short time before the writer saw him, hæmaturia, profuse and nearly constant, developed. A perineal section was made, as it was thought that the bleeding came wholly from the prostatic sinus, and not at all from the kidney. Severe secondary hemorrhage soon followed, and persisted for several days. The thyroid extract in five-grain doses by mouth, three times a day, was given, and the hemorrhage promptly and permanently stopped.

Hyoscine in the Treatment of Morphinism; Its Office and Value.—George E. Pettey declares that hyoscine not only occupies, but fills, when properly used, as important a place in the treatment of morphinism as does chloroform or ether in the practice of surgery. In a series of nearly 400 cases in which the writer has used this remedy, only in two or three cases has delirium or delusions of any kind been present as long as forty-eight hours after the last dose. In persons who have been treated by the methods he advocates, that is, through elimination of all toxic and effete material, and then the control of the acute withdrawal symptoms with hyoscine, the perfect recovery of all the mental faculties has been one of the most uniform and striking features. Hyoscine cannot be considered a substitute for morphine, and there is no reason for seeking such a substitute. It is unfit for prolonged use. By the use of hyoscine the sufferings of the days following the abrupt withdrawal of morphine are so alleviated that the patient can pass these few days in comfort, and escape the nerve strain and shock necessarily attending such an ordeal of suffering.

The Discrepancy between Clinical Manifestations and Pathological Findings in Appendicitis.—Nathan Jacobson refers to several cases of appendicitis, and concludes that we must not depend too much upon finding the so-called classic symptoms of the disease. It is evident that they are not always unfolded so that a positive diagnosis can be made early. We are not to be misled by apparently mild constitutional manifestations. Local signs are to be regarded as more significant, and can be relied upon to a greater degree than can constitutional manifestations. The persistence and the aggravation of any manifestation is to be viewed with alarm, and strongly suggests progression of the disease. The diagnosis of catarrhal appendicitis because of the apparently mild symptoms presented is often unwarranted. The restriction of the inflammatory process to the mucous surface of the appendix without ulcerative distruction thereof, at any point, is probably of infrequent occurrence. True conservatism, if by that we mean the conservation of life, is along surgical and not medical lines in every case of progressing appendicitis. The writer believes that every case in which the diagnosis of appendicitis can with positiveness be made, demands surgical rather than medical care. It is simply a question as to when the surgical operation should be performed. As a rule, the early operation affords the most encouraging prognosis.

Medical News, March 7, 1903.

Periduodenal Abscess Secondary to Ulcer of the Duodenum.—William Seaman Bainbridge declares that there is very scant information in medical literature on perforative ulcer of the duodenum, which does not involve the general cavity of the peritoneum. Although this disease is comparatively rare, there are, including the author's case, twenty-six on record. Twenty-two of these cases died without the diagnosis being made. In two an operation was performed, and the diagnosis made at the time that the abdomen was opened. One was cured. In another, diagnosis was accurate, operation performed, but the patient afterward died from the disease. In the author's case diagnosis was made, but the condition of the patient prevented surgical interference. The most frequent symptoms of this condition are vomiting, pain, tenderness and resistance in the epigastric and right hypochondriac regions, constipation or obstipation, sudden onset and shock. Many patients cannot lie on the right side, as it causes more pain. Usually there is a previous history of gastric or intestinal disturbances. A number of cases have followed a direct injury to the abdomen or some severe physical strain. Melæna or hæmatemesis are not common. They are more frequent in ulcer than in abscess. Temperature, if present, is generally slight. Complications may give rise to fever. It occurs more often in the male than in the female. It occurs in young or old. Of all the conditions which periduodenal abscess simulates, next to general peritonitis, appendicitis is the most frequent. The diagnosis is always difficult. If symptoms indicate the presence of ulcer (pain in the stomach two to six hours after eating, point of tenderness to the right of the twelfth dorsal vertebra, vomiting, specially hæmatemesis), and if sudden severe pain, marked increase of vomiting or collapse appears, operation is imperative. Exploratory laparotomy should be resorted to when abscess is probably present.

The Sanitary Aspect of the Mosquito Question.—John B. Smith states that a number of insects have been found as intermediate hosts for diseases of animals. Positively proved against mosquitos are yellow fever, filariasis, elephantiasis, and certain malarial fevers, all of which depend for their existence upon the presence of certain parasites in the blood or lymph of the individual affected. Malarial fevers are carried by the insects belonging to the genus Anopheles. The plasmodium malariæ is an animal, a protozoon, which lives and develops in a red-blood corpuscle. Its life period may be from two to four days. When ripe, it bursts and scatters spores in the general circulation. Each of these enters a red blood-corpuscle as soon as possible. For the transmission of malaria from one person to another, there is required: A patient suffering from the disease, in whose peripheral circulation are the sexed organisms or gametocytes; the proper species of anopheles at just the right time to draw these organisms into its digestive system; undisturbed development at a temperature not much below 80°, for at least a week. An uninfested individual, who is not immune, and who is bitten by the diseased mosquito. Dormancy is a matter of temperature. Anopheles selects preferably cellars for hibernation. These insects do not feed before they become dormant, and are, therefore, incapable of carrying over the plasmodium in any stage. The organism lies dormant in the blood of malarial patients ready to begin development when conditions favor. Unless there is a chance to get malarial blood, anopheles cannot of themselves produce malarial disease. The writer relates how certain breeding-places were treated twice with chloronaphtholeum and each time the larvæ were killed off. More than half of these breeding-places can be permanently cured at little expense, and most of the balance can be reached by compelling proper drainage, repair of gutters and other channels for carrying water. This field belongs to the local sanitary authorities. Good sanitation demands the removal of mosquito-breeding pools, and the abolishment of the mosquito pest. If all the local authorities throughout the State acted toward the same end, even a single year would show marked results. No mosquito larva lives in any ripple area in any body of water, and very few, indeed, escape their natural enemies in permanent bodies of water not too much choked with vegetation. The writer believes that the day is not far distant when the shore mosquito will be only an exceptional occurrence.

New York Medical Journal, March 7, 1903.

Expression of the Lid Margin as a Therapeutic Measure in Blepharitis and Its Complications.—P. Fridenberg makes it a point to pay special attention to the condition of the marginal glands, and to the detail of retention and septic inoculation in all cases of chronic blepharitis, as well as in those cases of superficial keratitis and corneal infiltrate, in which the presence of an infective lid element could be recognized. He has also made it a part of routine treatment to express, massage, and disinfect the lid margin in all cases of superficial inflammation in which there is the slightest evidence of retention, and to apply the same measures for diagnostic purposes in many instances to determine the necessity for further treatment of this sort. The clinical histories of several illustrative cases are given.

Incomplete Transverse Congenital Occlusion of the Vagina and a Theory as to Its Origin.—S. M. Brickner offers the following conclusions: (1) Transverse sæpta of the vagina are rare, occurring in about one in 5,000 cases, about .002 per cent. (2) They are derived from an inclusion by Müller's ducts of cells from the Wolffian duct or ducts after the formation of the genital cord, and are therefore epiblastic in origin. (3) Their perforation is proof of the normal conduct of Müller's ducts in all other respects. (4) Transverse sæpta of the vagina being normal in adult sheep, whales, dugongs, the manatee, and the chimpanzee, they represent in the human being a reversion, "a return to an ancestral type." Their function is purely speculative, but may have to do with the facilitation of conception; and when they appear in the human female may have a similar purpose in harmony with other minor defects of development. (5) The treatment of this condition is excision of the sæptum with

suturing of the cut edges. In unmarried women no treatment is necessary. If the sæptum is first seen in early pregnancy, it may be excised; if during labor, a crucial incision will be sufficient with subsequent removal of the sæptum. The prognosis for the child is usually bad unless the sæptum is incised early or unless it is not too strong to be burst by the advancing head; for the mother, it may result in serious lacerations or fatal hemorrhage.

The Present Method of Medical School Inspection in New York City.—C. Herrman gives the details of inspection as at present in vogue. The inspector visits the classroom once every week and examines each child. The examination is only partial, but sufficiently thorough to detect the acute exanthemata, and contagious diseases of the eyes and skin. Instruction is also given to the teachers, so that suspicious cases may be set aside for the inspector's special attention. Full details are given of the mode of procedure in case measles, scarlet fever, etc., are found. These children are sent home and visited by an inspector of the Health Department to confirm the diagnosis, and no such child may resume school attendance without the presentation of a certificate that the Department has disinfected the premises. No attempt is made to infringe in any way upon the rights of the family physician, and no prescribing is done. In order to prevent as far as possible the spread of diphtheria, each pupil is provided with an envelope in which his pencils and penholders are placed. When a case of diphtheria occurs in a class-room, cultures are taken, not only from the suspected throats, but also from the children sitting around the patient. Recently, nurses have been appointed to assist in the more crowded schools. They there carry out the treatment of such cases as impetigo contagiosa, ringworm of the face, acute conjunctivitis, etc. They also visit the homes of the pupils excluded on account of parasitic diseases of the skin and scalp, and treat these cases, also giving instructions to the mother, the object being that the child shall lose the least possible amount of time from school.

American Medicine, March 7, 1903.

A Slate Pencil Three and One-Half Inches Long Lodged in a Girl's Cheek for Three Weeks.—Stewart Le Roy McCurdy reports this unusual case. A girl of seven years had a fall downstairs, with a resulting wound in the face. The wound was closed with one stitch. It left a scar three-quarters of an inch external to the right side of the nose, on a line with the inferior margin of the alæ. After repair had taken place, a lump was discovered in the tissues beneath and external to the wound. This hard substance was in front of the malar. It was movable and had no connection with the maxilla. An exploratory incision was made, and a wooden slate pencil was removed. The anatomic relationship of this foreign body is of interest. As it penetrated the skin its point was deflected backward upon the anterior surface of the maxilla into the zygomatic fossa, underneath this arch toward the temporomandibular articulation, passing external to the coronoid process. It did not injure the external maxillary artery, but the point of the pencil must have reached if it did not pass it.

Direct Fixation in Fractures.—George W. Guthrie quotes various authorities on this subject, among whom is Estes, who says that in fractures, exploratory incision for the purpose of adjusting the fragments by sight, often absolutely indicated for proper treatment. The danger is not increased when proper aseptic precautions are observed. The open method, in proper cases, is the only safe method. Various writers use a clamp made on the principle of the "iron dog." A nickeled steel plate is described, which is used to maintain coaptation in compound fractures. In resections of the large joints, one or two nails or pins of steel, or some other metal, are a great help in maintaining apposition and immobility. If they are not silver, they should protrude from the wound, and be removed after a suitable time. There are numerous cases reported which have been successful, in which nailing has been done. Hatch is quoted as advocating the method of treating fractures by converting all compound fractures into simple ones, and, when necessary, making simple fractures first compound and then simple again.

The Treatment of Suppurative Inflammation of the Kidneys.—Frank Warner declares that numerous as are the causes of suppurative inflammation of the kidneys, there is still a considerable sameness in the producing factor of all: First, a plain catarrhal inflammation; second, an infection. (*a*) This infection, from within, conveyed through the blood; (*b*) from without, infection carried into the bladder through the urethra, perhaps by a catheter. The most frequent cause is a renal calculus. Pus in the urine, as a symptom, may mean many different things: An abscess in one or both kidneys, a pyonephrosis, an interstitial nephritis, or a pyelitis. Pyuria more often means that the pus comes from the bladder. As in all cases of pyelitis, the health is greatly impaired, a tonic, reconstructive course of treatment should be remembered, while attempting to render the urinary tract as sterile as possible. The writer is convinced in having examined many specimens of urine in cases of slight alteration of the normal urinary flow, that there are quite a few of these cases which are the result of a very mixed grade of pyelitis, and that many of the patients are promptly cured by timely administration of urinary antiseptics, especially if these are backed by a judicious tonic course of treatment.

Philadelphia Medical Journal, March 7, 1903.

Gangrenous Destruction of the Pituitary Body, with Disintegration of the Blood, Following a Fracture of the Sphenoid Bone and Subsequent Infection.—Eugene Wasdin reports this case. The patient was a man of twenty-four, who in a fall suffered a compound fracture of the lower jaw opening into the buccal cavity, and fracture of the body of the sphenoid through the sella turcica. Infection resulted in localized gangrene in the contents of the sella, and the lobes of the pituitary body, with general intoxication. There is some doubt as to the route of the infection from the fracture of the maxilla, but it must have been along the lymphatics of the inferior dental nerve and through the foramen ovale with the third division of the fifth nerve to the ganglion and into the line of fracture, destroying the pituitary body. Without the infection from the fractured jaw the sphenoidal fracture would probably not have resulted badly, and, although there were pain and vague head symptoms early in the case, it was only at the time of the local reaction at the side of the former that jaundice was noted, the first symptom of blood destruction. This came from adrenal insufficiency due to the primary changes in the pituitary body. The patient died on the twenty-second day after the injury. There was intense hæmatogenous jaundice. The influence of the pituitary body over the secretion of the adrenal glands through the cervicosympathetic system, and the importance of the adrenal secretion in the preservation of the integrity of the blood account for the facts in this case, so that it is not necessary to look for the source of a virulent toxin as the cause.

The Ductless Glands as Organs of the First Importance in Vital Functions, and Their Relationship as Such to Disease and Therapeutics.—Charles E. de M. Sajous embodies in his paper the results of investigations begun in 1889. His conclusions are: When the venous blood reaches the pulmonary alveoli, the marked affinity of the adrenal secretion in the plasma for oxygen causes it to absorb this gas from the alveolar air. The carbonic dioxide in the blood is thus forcibly replaced by oxygen and expelled with corresponding vigor The red corpuscles, after this operation, bathe in an oxygen-laden medium, and their hæmoglobin becomes converted into oxyhæmoglobin. The physiological function of the internal secretion of the adrenals is loosely to combine with the atmospheric oxygen in the lungs and to endow the blood-plasma with its oxidizing properties. The anterior pituitary body governs the functional activity of the adrenals and is directly connected with these organs through the cervicothoracic ganglia, the splanchnic nerves, and the semilunar ganglia of the sympathetic system. All general symptoms witnessed in disorders in which the blood is invaded by a poison of any kind are, in reality, manifestations of overactivity, insufficiency, or inactivity of the adrenals. The thyroid gland, the anterior pituitary body, and the adrenals are functionally interdependent and constitute a system, the "adrenal system," which has for its purpose to sustain physiological oxidation and the metabolic activity of all tissues. As to the function of leucocytes, he concludes that: Neutrophile leucocytes ingest proteids and certain hydrocarbons, sugar and starch, in the digestive canal, and convert these into peptone, myosinogen and fibrinogen granules. Eosinophile leucocytes elaborate hæmoglobin from the proteids, bilirubin, and iron, ingested by their parent-cells, the neutrophiles. They take part in the formation of the epithelium of the pulmonary alveoli and supply the underlying plasma with hæmoglobin. Lecithin is the active constituent of the myelin of nerves. The axis-cylinder contains plasma, the adrenoxin of which, by combining with the lecithin, liberates nervous energy. Basophile leucocytes convert fats derived from intestinal foodstuffs into myelin granules. Neutrophile leucocytes form: Peptones, which combine with adrenoxin to sustain general metabolism, *i. e.* the vital process; Myosinogen, which combines with adrenoxin to supply contractile energy to muscles; Fibrinogen, which combines with adrenoxin to supply heat energy to the blood. Eosinophile leucocytes form: Hæmoglobin, which loosely combines with adrenoxin to insure its storage in erythrocytes. Basophile leucocytes form: Myelin, the

active principle of which, lecithin, combines with adrenoxin to develop nervous energy. As to the splenopancreatic internal secretion: The greater part of the trypsin of the organism is formed in the splenic vein. The splenopancreatic internal secretion is represented by the trypsin which reaches the portal vein by way of the splenic vein, and which continues in the blood-stream the cleavage processes begun in the intestinal canal. The main function of the splenopancreatic secretion, trypsin, is to protect the organism from the effects of bacteria, their toxins, and all toxic albuminoids, including vegetable poisons and venoms. In regard to the pituitary body, the writer found that while the anterior pituitary body insured oxygenation of the blood through the adrenal secretion, the posterior pituitary body adjusted the functional activity of all organs through the nervous system. In regard to disease, the organ primarily at fault in pulmonary tuberculosis is the anterior pituitary body. Vulnerability to any disease, whether inherited or acquired, means insufficiency of this organ, that is to say, of the adrenal system. In the treatment of tuberculosis, adrenal stimulants will often prove inadequate if the alkaline salts are not administered simultaneously, while the use of alkaline salts without adrenal stimulants will prove unavailing, though perhaps beneficial for a time. The writer then considers fever. To administer antipyretics is to defeat Nature's effort to relieve the organism of pathogenic elements. Steadily, as the febrile process advances, the alkaline salts are consumed, and, being indequately renewed, the vital and defensive functions are increasingly hampered until life ceases. The power of the organism to antagonize the constitutional effects of pathogenic germs, their toxins and other poisons, is directly proportionate, all else being equal to the functional efficiency of the adrenal system. When a favorable reaction does not follow the use of saline solution, it is because the adrenal system also requires direct stimulation, such as that afforded by strychnine, digitalis, etc., administered subcutaneously.

Deutsche medicinische Wochenschrift, February 12, 1903.

Priority in the Discovery of the Dysentery Bacillus and the Serumtherapy of Dysentery.—K. Shiga claims this, and says that the work of Kruse, recently published, adds nothing new to the subject except the identity of the bacillus found in Germany to that previously described in Japan. Shiga proves his claims by quotations from Kruse's previous publications and those of v. Drigalski and Lentz. The same remarks apply to the serumtherapy of this disease.

A Stomatitis Epidemic in South Africa During the Recent War.—J. C. J. Bierens de Haan describes an epidemic which broke out among the troops in South Africa, and in many of the inhabitants who came in contact with the same. The outbreak of the disease took place simultaneously with a great shortage in the supply of salt, and the trouble rapidly subsided when this article was supplied in sufficient quantity. The stomatitis was of the ulcerative variety, but was not attended by any constitutional symptoms. As a rule it was readily cured by the employment of mild antiseptics and astringents. Bacteriological examination of the cases was not possible, and hence the primary etiology is unknown. An accessory cause was undoubtedly the deficient supply of salt above noted.

Berliner klinische Wochenschrift, February 16, 1903.

Hardening of Children.—Walter Krebs takes exception to the recently expressed views of Hecker upon this subject. In judging the effect of the water treatment upon children, Hecker furnishes no observations upon the power of the children to resist cold *previous* to the institution of the treatment. All control observations were hence excluded. Furthermore, children which have been submitted to the treatment are undoubtedly more exposed by their parents or care-takers than those who have not been treated. Similar conditions, therefore, not being present, an opinion is not possible concerning the liability for "catching" cold between so-called "hardened" and "non-hardened" children.

Acute Inflammation of the Sigmoid Flexure.—A Bittorf reports two cases as caused by impacted fæces. In both cases the inflammation was probably of the catarrhal type and readily succumbed to the action of cathartics (castor oil). The general symptoms consisted of fever and the concomitant appearances. Locally there was meteorism and a distinct area of circumscribed resistance in the left iliac region. No vomiting was present. The action of the bowels had been regular up to the day of the attack. The amount of indican in the urine was increased. In this class of cases the differential diagnosis lies between sigmoiditis and appendicitis, perinephritic abscess, and, in women, inflammatory diseases of the uterus and its appendages. Sigmoiditis, of itself, may also proceed to abscess formation. The diagnosis of such formation is somewhat difficult, although to total enumeration of the leucocytes, as in appendicitis, may be of aid. The prognosis is usually favorable. Recurrences are, however, somewhat frequent. The treatment consists in the administration of cathartics, except in those cases in which abscesses have formed, when opium should be given and local applications of ice applied.

Münchener medicinische Wochenschrift, February 17, 1903.

A Case of Blower's Paralysis.—Ed. Stadler reports the case of a bass trumpet player, who after excessive work became unable to perform upon his instrument, in that after playing for a few minutes he could not produce the high-pitched tones, and thus played out of tune. For all ordinary purposes there was not paralysis of the lips or facial muscles. The portion of the lower lip covered by mucous membrane was somewhat more susceptible than normal to pressure, and when blowing upon his trumpet saliva constantly dribbled from the corners of the mouth. The general condition of the patient was excellent. Strümpell, Turner, and Oppenheim have previously reported similar cases. They are to be regarded as a variety of artisan's neurosis.

Amaurotic Idiocy.—C. Gessner reports a case in Bamberg. This disease is rare in Germany, but has been observed by several authors in England and America. The patient was one year and a quarter old, and until seven months previous had been apparently perfectly well. At that time there developed a weakness and stiffness of the lower extremities, which gradually increased in severity. The back muscles and those of the neck and head became progressivaly involved, so that before long the child lay upon the bed with a spastic paralysis of nearly all the muscles of the body. Vomiting was not at first present, but developed later. Ophthalmoscopic examination revealed the presence of the characteristic retinal changes of this disease which have been described by other authors. Death took place after about eight months of sickness.

Hysterical Tachypnœnia with Organic Cardiac Lesions.—H. Curschmann, Jr., reports a case which shows that hysterical accelerated breathing may occur in association with organic cardiac lesions without being in any way dependent upon the same. The patient gave a history of repeated attacks of rheumatism, and presented a non-compensating mitral regurgitation of long standing. The attacks of hysterical breathing occurred at frequent intervals, the number of respirations varying from 40 to 100 per minute. During the attacks the cardiac frequency was about 80 per minute. Cardiac stimulants (digitalis, etc.) in no way alleviated the attacks, but they readily succumbed to treatment with valerian and a mild faradic current (suggestion). During the attacks there was present hysterical meteorism, and the facial expression and general behavior of the patient was characteristic of hysteria. The value of an accurate diagnosis in such cases is apparent, for the whole course of treatment is vitally influenced thereby. Another case is reported which was of traumatic origin. No cardiac valvular lesions were present, but the myocardium was degenerated. Here, during the attack, the cardiac frequency was from 108 to 120 per minute. The administration of strophanthus improved the myocarditis and lessened the pulse rate, but in no way reduced the frequency of the respirations. The latter was somewhat improved by suggestion.

Arsenic, a Normal Element of the Living Cell.—According to recent researches of Armand Gautier, it has been established that small quantities of arsenic are found in man, principally in the thyroid gland. But these researches have been contradicted by several authorities. Gabriel Bertrand, however, in his experiments on animals, has been able to demonstrate in an absolute manner that arsenic is a normal element of the living cell, which is found in all animals and in all organs. Besides the biological interest of this fact, it has great importance from a medicolegal point of view.—*Le Bulletin Médical*, February 4, 1903.

A Case of Pseudobulbar Paralysis Due to a Unilateral Cerebellar Lesion in a Child of Five Years.—Luigi Concetti concludes that his case, which is perhaps the only one that has ever been described in the pathology of childhood, has positively demonstrated the possibility of a bulbar paralytic syndrome, with absolute structural integrity of the bulb. This syndrome can occur from a unilateral lesion of the cortico-ganglional centers. For the production of this pathogenetic condition, the unilateral lesion must be situated profoundly enough to destroy not only the cortico-ganglional-bulbar paths, but also those which originate in the opposite hemisphere, and reach the bulb

after decursating in the corpus callosum.—*Il Policlinico*, January, 1903.

Arterial and Capillary Nævi in Affections of the Liver and Biliary Passages.—Gilbert and Herscher speak of the arterial and capillary angiomata that are encountered in patients suffering from affections of the liver and biliary passages, alcoholic and biliary cirrhoses, biliary lithiasis, and jaundice. The arterial angiomata are found on the face and hands; they have an elevated center of violent color, from which small vessels radiate out. They look like vascular stars. The capillary angiomata are more generally found on the trunk, and are in the form of small red stars, surrounded by a white areola, scarcely visible. The arterial angiomata beat perceptibly, but this is not true of the capillary form. Histologically, the arterial angiomata are composed of a mass of vessels with irregular lumen. The capillary nævi consist of dilated capillaries. The arterial angiomata are the rarer form.—*La Presse Médicale*, February 7, 1903.

Phosphorus in the Treatment of Rachitis.—Luigi Concetti gives directions for preparing the solution of phosphorus to be used to avoid possible poisoning. Properly dissolved and administered, he considers it the surest and most rapidly successful treatment for rachitis. In from one to two months the symptoms proper to rachitis itself, such as pain and impaired mobility, are overcome, and symptoms referable to the nervous system, such as laryngeal and respiratory spasm, hyperæsthesia, irritability, night terrors, tetany, etc., disappear, or are greatly reduced in a few days. It is probable that the phosphorus acts upon the toxic products which on the one hand attack the bony system and on the other the nervous system. The author cites a number of cases in support of his opinion as to the value of phosphorus, and believes that cases of failure are exceptional.—*Rivista di Clinica Pediatrica*, January, 1903.

The Nature of the Phenomena of Rotation around a Longitudinal Axis in Animals with Unilateral Lesions of the Cerebellum.—Sergio Sergi concludes, from his experimentation: (1) That the phenomena of rotation around a longitudinal axis in animals with a unilateral mutilation of the cerebellum is of the same nature as the movements in a riding school, and the rotary motion of the hand of a clock. (2) All these movements are produced by an absence of motor and sensory equilibrium between the two halves of the body. (3) In the rotary movements of animals from whom half of the cerebellum has been removed, the motor equilibrium, which is the mechanical condition of the phenomena, is represented either by hypertonicity and hypervitality of one side over the other, or by the atony and asthenia of one side; the sensory lack of equilibrium is shown by visual and labyrinthine vertigo. —*Il Policlinico*, January, 1903.

The Functional Power of the Liver in Children as Determined by Experimentation with Levulose.—Domenico Crisafi, from his experiments on healthy children, concludes that there is no relation between the amount of levulose utilized by the economy and the weight of the body. From his experiments on children suffering from various diseases he concludes: (*a*) That the amount of levulose to be administered should be from 25—40 gm. in children under five years of age, and from 40—60 gm from five to twelve years. (*b*) In acute infective diseases the liver usually retains its functional powers. (*c*) Nephritis and slow tuberculous processes appear to occasion the most disturbance to the hepatic function. (*d*) The phenylhydrazin test is the most delicate of all for the discovery of even slight traces of levulose in the urine. (*e*) Levulose constitutes the best test of the functional powers of the liver.—*Rivista di Clinica Pediatrica*, February, 1903.

Fibromata of the Broad Ligament.—Henri Strohēker states that these tumors may have an abdominal evolution, abdomino-pelvic or purely pelvic. As to their origin, these are recognized: Interstitial fibromata of the broad ligament, called primitive fibromata, without uterine connection; pediculated fibromata (polyps of the broad ligament); sessile uterine fibromata, which rise from the lateral border and penetrate the ligament; pediculated uterine fibromata, springing from one of the segments of the uterus; fibromata which, springing from the adnexa, or round ligament, grow into the interior of the ligament The functional symptoms, and especially the complications, present a considerable interest. The diagnosis is often very difficult to make. The course and duration are extremely variable. The prognosis is not absolutely good. Every tumor which gives rise to phenomena of compression ought to be operated upon. The method of choice is the abdominal route.—*Annales de Gynécologie et d'Obstétrique*, January, 1903.

Generalized Cancer of the Stomach.—Roque and Bancel report this case. The patient was a young woman who had succumbed to cancer of the stomach. The affection was of very rapid evolution (four or five weeks). At autopsy an enormous tumor was found, which had invaded the lumbo-abdominal, mesenteric, and mediastinal ganglia, as well as the pancreas, spleen, suprarenal capsules, and the aorta and vena cava, which were compressed and contracted. The diagnosis could not be made. The existence of a pulsatile tumor and the perception on auscultation of a double souffle suggested, for some time, an aneurysm; these symptoms were due to compression of the aorta. Later, the possibility of tuberculous peritonitis was thought of on account of multiple adenopathies and fever. The appetite was unimpaired to the last; intolerable pain necessitated the use of morphine, there was absence of cachexia and abundant ascites. Vomiting was frequent in the last stages. Death occurred suddenly after this rapid evolution of the new growth.—*Lyon Médical*, February 8, 1903.

The Pathogenesis of Gastric Tetanus.—Luigi D'Amato reports the case of a man who suffered from gastrosuccorrhœa which had lasted five years and which was not amenable to treatment. He was suddenly taken with tonic contractions of the upper limbs, trismus, and other symptoms of tetanus, and died in coma. In order to ascertain whether the theory of gastric autointoxication in this disease was correct, the author instituted a series of experiments on animals. The conclusions which he reaches are the following: That in the case reported the cause was undoubtedly autointoxication, because in animals poisoned by gastric contents, the same symptoms were produced as in the patient—myosis, respiratory disturbances, contractions, anuria, and trismus. Moreover, the various organs of the patient, as the nervous centers, the liver and the pancreas showed the same lesions as those which we are accustomed to find in various intoxications. The author is not willing to generalize on the matter since other investigators have obtained results differing from his.—*La Riforma Medica*, February 4, 1903.

A Rare Case of Intestinal Occlusion.—T. Calabi and L. Gaiardoni report the case of a man sixty years old, who had previously suffered from varicose ulcers of the legs, and from an inguinal hernia which had not been operated upon. For about a year he had been subject to periods of violent pelvic pain, which made their first appearance after a severe contusion of the upper pelvic region. These pains would disappear after rest in bed, and the administration of a purgative oil. Finally the attack failed to yield to this treatment, and was accompanied by severe vomiting. The patient's general condition was so grave that no operation was possible, and death ensued. At autopsy it was found that a portion of the intestine had entered the bladder through a perforation about 8 cm. in circumference, the edges of which were swollen, smooth, grayish white and indurated like cicatricial tissue. It is supposed that at the time of the contusion the intestines were driven in through the thinned walls of a greatly distended bladder. It is probable that the mucosa of the bladder was not ruptured, but that a species of hernia was found, which at a later period ruptured and caused the fatal issue.—*Il Policlinico*, January, 1903.

Melanotic Tumor of the Skin; Ganglionic Invasion of Slow Progress.—Roche describes a patient of forty-eight years who had noticed about five years before the development of a small blackish tumor, in the left plantar region. This growth was about the size of a cherry and painless. It increased in size slowly. The patient made a little hole in his shoe, in which the tumor could lodge. At the end of a year and a half the size had increased to that of a two-franc piece. The tumor was then removed by the thermocautery. The wound healed normally, but in fifteen days there developed in the left groin a group of ganglia as large as nuts, painless, but causing, in walking, a sensation of tension in the inguinal region. The ganglia were removed. They were blackish. For two years the patient was in good health. Then he began to feel, when he walked, a painful feeling of heaviness in the left iliac fossa. A tumor was found here, hard, bosselated, and adherent to the pelvic walls. By rectal examination it was found to reach deeply into the small pelvis. On operation the tumor was found so intimately connected with the large vessels that, after some of the ganglia were removed, the wound was closed and drained. These ganglia are blackish on section. Although the clinical history pointed to melanotic sarcoma of the skin, the histological examination, without contradicting it, does not corroborate the clinical diagnosis. The exact nature of the tumor has not yet been determined. The slowness of ganglionic invasion is an interesting and unusual feature.—*Journal de Médecine de Bordeaux*, February 8, 1903

Annals of Surgery, February, 1903.

Cases Illustrating Some Important Points in the Diagnosis and Treatment of Abdominal Contusions Associated with Visceral Injuries.—G. E. Brewer reports nine cases, three of which recovered. The cases variously presented ruptures of the liver, spleen, kidney, intestines, internal iliac vein, innominate, bone, ureter, and bladder. This class of injuries calls for prompt operative measures. In every case, one of the arm veins should be exposed so as to allow of immediate saline infusion. Brewer believes that the treatment of extensive fractures of the spleen by pressure and packing is preferable to splenotomy, it being equally as effective in arresting hemorrhage. It is accompanied by less shock, saves time, and preserves an important organ. The same general principles apply to the liver. From a study of twenty cases of visceral injury following abdominal contusion, and verified by operation or autopsy, the author finds that the most important symptoms present in the earliest stage are pain, tenderness, and muscular rigidity. The association of these three is almost pathognonomic of peritoneal irritation. In the absence of spontaneous pain, localized tenderness with rigidity is strongly suggestive of visceral injury. Of the three, muscular rigidity is the most reliable and sometimes the only sign present. In such instances it may be looked on as nature's effort to protect an injured organ from further irritation.

Other signs are vomiting (more common in injuries affecting the stomach and upper bowel), free fluid and free gas in the abdominal cavity. Concerning the diagnostic value of localized signs and symptoms, the author offers the following: If, following an abdominal contusion with or without evidences of superficial injury, there are localized pain and rigidity over the epigastrium with the presence of free gas in the peritoneal cavity, a rupture of the stomach may be suspected. If, under the same circumstances, their is pain and tenderness limited to the right hypochondriac region and rigidity of the upper half of the right rectus muscle, with free fluid in the peritoneal cavity, and with a progressive weakness, pallor, cold perspiration, restlessness, air hunger, thirst, and a rapid, weak pulse, rupture of the liver with severe hemorrhage is to be inferred. The same symptoms and signs limited to the left hypochondrium suggest a rupture of the spleen. Pain and rigidity about the umbilicus or in the lower part of the abdomen without other symptoms suggest rupture of the intestine. The diagnosis is rendered more probable, if, in addition, free gas can be demonstrated in the peritoneal cavity. Pain in the hypogastrium, with vesical tenesmus and the passage of a small amount of bloody urine or an empty bladder, indicate rupture of that organ, while pain in one flank, with hæmaturia and the formation of a retroperitoneal exudate, suggests contusion or rupture of the kidney.

An Operation for the Radical Cure of Aneurysm Based upon Arteriorrhaphy.—R. Matas submits the following propositions: (1) That the recognized advantages for the radical operation for the cure of aneurysms of the peripheral arteries, as demonstrated by the statistics of the last decade, can be greatly increased, and the sphere of application of this operation can be broadened by the adoption of the method of suture and obliteration of the sac instead of the classical ligation of the arteries, with or without extirpation, as hitherto practised. (2) That the closure of the arterial orifices which supply the aneurysmal sac, whether these be single or multiple, by means of suture, and within the aneurysmal sac itself, greatly simplifies the technique of the radical operation, and is a reliable means of securing hæmostasis. (3) That in favorable cases—and the saccular aneurysms with a single orifice communicating with the lumen of the larger arterial trunks are the most favorable—it is possible, by careful suture, to obliterate the aneurysmal opening without obstructing the lumen of the parent artery, thus protecting the limb from the risk of gangrene. (4) It is also possible in favorable cases of fusiform aneurysms of traumatic origin, and in all those in which the sac material is healthy and pliable, to restore the lost continuity of the artery by building a new channel which will connect the two main orifices of communication and restore the interrupted circulation in the parent vessel. This result can be obtained by utilizing the sac in the manner previously described by the author. (5) That the fear that atheroma and other degenerative changes will interfere with the healing and repair of the arterial tunics has been greatly exaggerated is shown by the abundant experience of the aseptic period in the ligature of sclerotic arteries in continuity, in the absence of secondary hemorrhage in the amputated stumps of the aged, diabetic, and other arterially diseased subjects, and is still demonstrated more fully by the observations and statistics of the partisans of the radical operation by extirpation who have reported numerous successful results in spontaneous as well as in traumatic aneurysms. (6) The fallacy and dangers of the old operation of Antyllus lie (*a*) in the fact that the preliminary ligation of the main artery above and below the sac will not always control the bleeding from the collaterals which often open into the aneurysm or into the main trunks between the orifices in the sac and at the seat of ligature. This compels a more or less extensive dissection of the sac out of its bed as one of the necessary features of the procedure, in order to secure all the collateral vessels that empty into the sac, unless the uncertain process of plugging the openings and packing the sac itself is resorted to. If the sac is dissected, as is usually done to secure the collaterals, the difficulties of the operation are increased, and the vitality of the limb is endangered by interfering with the collateral circulation which, in many types of aneurysm, is most freely developed in the neighborhood of the sac. (*b*) Another serious objection to the old Antyllus operation is that the sac remains an open cavity in the bottom, being packed or drained and allowed to heal by granulation with the danger of infection suppuration and secondary hemorrhage. (7) The uncertainties and dangers of sac extirpation are even more apparent on account of the greater risk of injury to the accompanying satellite veins and nerves, which blend with the sac so that only a partial extirpation is at times possible. Moreover, there is the danger of interference with the collateral circulation with the risk of mortification in the distal parts. All of these risks are avoidable, or at least reduced to a safe minimum, by the author's method.

Archives of Pediatrics, February, 1903.

Pilocarpin in the Treatment of Scarlet Fever.—E. W. Saunders holds that this drug should not be used where there is coma or threatened coma, cardiac weakness, or any embarrassment of the respiratory function. The peculiarly beneficial effects of pilocarpin in scarlet fever are due to its effects upon the salivary and muciparous glands, coupled with the absence, generally speaking, of all tendency to myocardial or neural degeneration, and of pulmonary complications. The beneficent effects of the drug are moderate reduction of the temperature (when not hyperpyrexial), relief of suffering due to the parched and fissured mouth and lips, rapid improvement in the state of the oral and faucial mucous membranes, and prevention of glandular infection. If the nasal membrane be infected, there is no good result to be expected so far as this condition and the subsequent aural complication are concerned.

Two Instructive Cases of Cerebral Pneumonia and Their Treatment.—Louis Fischer reports two cases in which the most noteworthy symptoms were the following: Unilateral spasms, twitchings of the muscles of the shoulder and arm, and of the leg and foot, constantly present; twitchings of the muscles of the eye and a constant rolling of the eyeball; the head was thrown backward; the patellar reflex was absent, and the plantar reflex was slight on the affected side; distinct evidences of pneumonia, bronchial breathing, and marked dulness on percussion; convulsions and marked stupor later in the disease. When the crisis appeared in the pneumonia, the cerebral symptoms subsided. Marked nervous depression and extreme hyperæsthesia of the body, which continued for weeks after all inflammatory symptoms had subsided. Cold packs were given, and creosote carbonate administered in one case. The vital point in the treatment consisted in giving a supporting diet, consisting of eggs beaten up with sugar and Tokay wine, concentrated soups, and milk predigested with peptonizing powder.

The Prognosis of Tuberculous Peritonitis in Children.—G. A. Sutherland concludes from his studies that in uncomplicated tuberculous peritonitis the prognosis is good. When tuberculous pleurisy is present, the prognosis is still favorable. The prognosis is rendered less favorable in the case of (*a*) a strong family history of tuberculosis, (*b*) an infancy passed under bad hygienic and dietetic conditions, (*c*) a constitution of feeble resistant power, (*d*) a history of severe infective illness in early life. The prognosis is rendered less favorable in the presence of one or more of the following symptoms: continuous pyrexia, rapid wasting, persistent diarrhœa, rapid pulse, or recurrent acute exacerbations. Also in the presence of one or more of the following complications: tuberculous ulceration of the bowel, extensive caseation of the mesenteric lymph nodes, or of tuberculous masses, localized suppuration from infection through lymph nodes, or the intestine; obstructive symptoms from bands or matting of the intestine. The prognosis is bad in case of rupture of a suppurating lymph node, or the perforation of an intestinal ulcer into the peritoneal cavity; pulmonary tuberculosis, tuberculous meningitis, and general miliary tuberculosis. In tuberculous peritonitis the prognosis is not appreciably affected by simple laparotomy.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held March 5, 1903.

ANDREW H. SMITH, M.D., PRESIDENT.

Intracellular Catalytic Processes in the Pathogenesis of Cancer.—Dr. JOHN C. HEMMETER of Baltimore presented a paper with this title. He said it was now accepted as one of the truths of both physiology and pathology that the cells of the mammalian organism could change their form and structure under certain conditions. Physiologically they might do so according to age and various extrinsic and intrinsic influences. It was often impossible to draw a sharp line of demarcation between changes of this kind, which were normal, and those which were abnormal. Cancer pathogenesis was, in part at least, the problem of the growth of cells under different conditions, and hence one had a right to expect that the solution of the problem might be aided by the adaptation of recent discoveries in physical chemistry on cell growth. Molecule for molecule the cell contained within it everything that the entire organism contained. The two principal theories concerning the pathogenesis of cancer were the histogenetic and the parasitic. Recent contributions from the Harvard Cancer Commission tended to invalidate the parasitic theory. The histogenetic theory did not permit of experimental proof of its correctness. Thiersch had sought to find the cause of cancer in a reduced resistance of the connective tissue. Another theory assumed that there was a normal resistance to growth, and that when this was removed carcinoma was the consequence. All of these theories had in common the view that malignant neoplasms were due to some indefinite power of growth within the cells. The speaker said that while we were not quite ready to deny the bacterial theory he did not see that we could indorse it. The growth in a parasitic disease was never disseminated by the cell, but by the parasite, whereas in malignant tumors the dissemination of the disease was by the spreading of the cell. In no infectious disease was it found that cells from the primary inflammation were driven about. According to the parasitic theory, the parasite must live in the cell; and as the cell must multiply indefinitely the parasite could not seriously injure the cell. It was necessary to assume that every cell contained a parasite, and that each parasite multiplied just as rapidly as the cell; in other words, this condition necessitated that the cycle of development of the parasite must coincide with the rate of multiplication of the proliferating cells. It was safe to say that the implantation of malignant neoplasms had been successful only in animals of the same species. Personally, he was of the opinion that such implantation should be not only into an animal of the same species but even into the same organ from which it originally came. Typical congenital neoplasms had been reported in children whose parents were not affected with malignant neoplasms, and it was difficult to understand how such a malignant growth could develop during intrauterine life, if the parasitic theory were correct, without the parent participating in this growth.

Experimental Production of Cancer.—The speaker said that he had taken up the study of the experimental production of cancer about three years ago, having been led to do this by receiving a carcinoma from the stomach of a dog. It was remarkable how much surgical damage could be done to the stomach of the dog and how completely it would be repaired. Silbermann had found that by denuding the gastric mucosa in the neighborhood of the pylorus and depriving the animal of hæmoglobin by the injection of pyrogallic acid a permanent lesion could be obtained. This observation he had confirmed, as well as that of certain observers to the effect that such an ulcer sometimes became carcinomatous without any effort at inoculation. Continuing his experiments he had found that four out of ten dogs so treated were subsequently inoculated successfully with carcinoma, and that, in another series, five out of ten dogs developed carcinoma around the edges of the gastric ulcer by the injection of a cell-free extract of carcinoma. All digestive ferments were just as much catalyzers in their action as was colloid platinum—that is, they accelerated or retarded chemical action without entering into the resulting chemical product. The percentage of salt in normal salt solution was theoretically that of the blood plasma, and one would expect that a cancer cell would act like a normal blood cell in the blood plasma or in normal salt solution; however, it had been found that the cancer cell became swollen when so treated. This had led to certain studies in osmotic pressure. These changes in the cancer cell in normal salt solution were very suggestive, because they indicated an inherent tendency to growth. The immediate causes of cell subdivision were as yet unknown. According to Virchow, it was formerly held that not only the form of the cells but their growth could be affected by external stimuli. Weigert held that tissue growth might result from the removal of the normal inhibition of tissue growth. All of the chemical processes in a cell were conceived to be due to catalytic agents. The growth of a cell necessitated the synthesis of albumin. All of the intracellular and constructive and destructive processes probably went on by virtue of enzymes. Modern bacteriologists had imagined the structure of the cells to be like soap-foam, though infinitely more finely subdivided. If normally a cell were made up of myriads of small cells each containing its separate enzymes, then it was easy to understand that very slight damage, causing a breaking down of the partitions and a mingling of enzymes which should be kept separate, might cause anarchy in a previously orderly household. This was the chemist's conception of the origin of a malignant neoplasm. Enzymes were affected by heat, a fact which was of interest in connection with his experiments in the production of cancer, for he had found that after heating the solutions to be inoculated up to 60° C. he could no longer succeed in artificially producing cancer. Somewhere between the cavity of the stomach and the intestines the peptones and albumoses must be reconstructed again into albumin in order to be available for the uses of the system, and it was probable that this was affected by the same enzymes which broke them down. It should be remembered that the end products of digestion were peptones and albumoses, and that these substances were not found in the blood; indeed, peptone was a poison, and if injected into the jugular vein of an animal would cause the death of that animal. This reversibility of the enzymes just referred to, although not fully demonstrated, was probably a fact, and it probably afforded a self-governing factor in cell growth. In Virchow's great work on cellular pathology three nodes of extension of cancer were recognized, viz., (1) immediate extension; (2) dissemination by metastasis; and (3) a transference by means of liquids which possessed the power of creating an infection, thus causing the individual parts to form a reproduction of the same mass which was originally present. The speaker thought it possible that in this third mode of extension Virchow saw the possibility of the dissemination by means of catalysis or the action of enzymes. It was possible that the serum contained a substance capable of destroying cancer cells unless the latter were present in inordinate quantities. If this were true, it was most important to discover a means of augmenting this natural defense. At this point the speaker digressed to say that while the results of his experiments had presented the histological appearance of cancer, he did not wish to be quoted at the present time as claiming that he had actually produced cancer experimentally. He had certainly produced a histological condition closely resembling carcinoma of the stomach, but it was possible that if the animal had been kept alive longer this abnormal proliferation would have

disappeared, or, at least, would not have continued to grow.

Primary Cancer of the Appendix.—Dr. A. V. Moschcowitz read this paper. He said that reports in the literature of primary carcinoma of the appendix vermiformis practically dated back only to 1896. There were yet only about twenty such cases on record. The clinical picture was still very meagre, though he had had the opportunity of operating upon three cases of undoubted primary carcinoma of the appendix in the past eighteen months. The majority of the reported cases were of recent date, practically within the last six years. That the gross appearance of the appendix alone was not sufficient for the recognition of the condition was shown by the report of three cases in which the existence of cancer of the appendix was not even suspected until after microscopical examination. He believed this pathological condition was far more frequent than appeared from the statistics hitherto published. Only sixteen of the published cases were available for the study of the clinical picture. In eleven cases the patient was under the age of thirty, showing that carcinoma of the appendix developed at a relatively early age. This really meant that carcinoma of the appendix was most common at that age when acute inflammation of the appendix was most frequent. There was apparently no relation between the length of the appendix and the occurrence of carcinoma. In the reported cases the tumor had varied from a microscopical size to that of a marble. The variety of carcinoma could not be ascertained from the reported cases, although the prevailing type appeared to be adenocarcinoma. In his own three cases, two were medullary carcinoma and one adenocarcinoma. In all of the reported cases the tumor was situated in the mucosa, and from this point infiltrated the other tissues of the appendix.

The weight of evidence seemed to be in favor of the view that the inflammation of the appendix was primary, and the carcinoma secondary thereto. It should be noted that the carcinoma began in the mucosa, that tissue in which the inflammation was most marked. Primary carcinoma of the appendix was more frequent in the female than in the male in the proportion of four to one. In one reported case of carcinoma of the appendix after death metastases were found. In one of his own cases the carcinoma was removed nineteen months ago, and at an operation on the same individual, done only a few weeks ago, there was no recurrence of the disease.

Dr. Robert F. Weir said that he had first encountered primary carcinoma of the appendix in the year 1894. The appendix had been removed in the quiescent stage, without any suspicion of malignant disease being present, but to his surprise the pathologist reported that there was a carcinoma at the tip of the appendix. He had been able to keep this patient under observation for three years, and during that time there had been no evidence of recurrence. While Dr. Hemmeter's masterful paper had presented this complex subject of the pathogenesis of cancer in a remarkably lucid manner, he could not help feeling disappointed because theories rather than facts had been laid before us. The Harvard school had presented the subject in a way which seemed to settle the question, and the Buffalo school had done the same thing, but in a very different way. Practical men were still waiting eagerly for the facts that must eventually come from so much earnest scientific research.

Dr. James Ewing said that he had been extremely pleased at the cold, philosophical statements made in Dr. Hemmeter's paper. The most important feature of that communication was that dealing with the transplantation, or perhaps the actual development, of carcinoma by experimental means. This brought up the question of what constituted a cancer. Dr. Hemmeter had carefully guarded his position in this respect by saying that he had succeeded in producing what was recognized by histologists as adenocarcinoma of the stomach of a dog. He would say that if Dr. Hemmeter wished to prove this fact to a third party the only satisfactory way was to demonstrate the specimens themselves. He made this statement with all due deference to the author's opinion, and with full appreciation of the sincerity of the claim. The photograph presented to him a condition which showed chiefly an adenomatous character, and before concluding that this was a carcinoma he would like to know how often such a condition might be found in dogs in which an artificial gastric ulcer had been produced in this way. The photograph was suggestive, but it was far from conclusive proof to his mind of the presence of carcinoma. He would feel better satisfied if the tumor were more of the type of a pure carcinoma than one of the adenomatous type. With regard to the method of experimentation, he would criticise the manner in which the fluid had been prepared for injection. There was no reason for the assumption that the filtered fluid was bacteria-free, because it was known that a few microorganisms would pass through even the finest porcelain filter. We had been told that when the cancer cells were placed in normal salt solution they swelled up, indicating an increased capacity for multiplication. This was certainly an interesting observation, but with regard to its significance it might be impossible to draw any conclusions. He would like to know whether other cells had been tested in this way, for other cells of the body varied considerably in certain anatomical and pathological states. It was quite probable that the bulk of the products produced by cells were referable to the action of ferments, and the group of processes included in the term, cell catabolism, was dependent upon the action of these ferments. Recently there had been added to the chemistry and physiology of the cell certain processes which were not due to catalysis, but were related to the subject of immunity. Many observers were of the opinion that these theories of immunity would bring out certain new processes in the cells which would have an important bearing on the pathogenesis of cancer. For a long time he had been interested in this subject of the catabolism of tumor cells. According to this theory, the cells in tumors had lost the power of work and had assumed an excessive capacity for growth. This meant that they had lost the presence of, or the activities of, these catalyzers or ferments. On account of the synthetic building up of new molecules in the cells there were excessive efforts at multiplication. If it were a fact that tumor cells had lost largely their power of work and were devoting themselves to cell growth, then there should be very concrete evidence of this. Some tumors had apparently lost most of their function, as for example, cancer of the breast in the advanced stages, when there was little tendency to the production of milk. It was not true, in his opinion, that the cells had necessarily lost any considerable portion of their capacity for work. In other tumors the ordinary functions of the cells were not lost, but were even made use of in the body. For example, there were malignant tumors of the liver in which the manufacture of the bile still continued. Perhaps the most striking example occurring to him at this moment was to be seen in melanotic epitheliomata. These tumors were probably derived from the epithelial cells of nævi, which, in their earlier states, were highly pigmented. The metastases from these tumors showed groups of cells which were even more highly pigmented than the original cells, and the more malignant this growth became the more highly was it pigmented. His own conception of the tumor problem involved largely the idea of tissue tension. This included the mechanical pressure of one cell upon the other, the effect upon function and the distribution of nutriment upon the cells. When the tissue tension was lost the tumor process developed. The essential nature of this process still remained in obscurity. He would admit that the extemporaneous discussion of such a difficult subject was not very profitable, and perhaps he would change his opinion in some respects after he had

devoted several hours to the quiet study of Dr. Hemmeter's paper.

Dr. HEMMETER said that the main object of his paper was to elicit discussion. There could not help being a diversity of opinion upon problems so intricate. Dr. Loeb of Chicago had recently successfully transplanted in rats typical sarcomata of the thyroid, and had continued this for upward of forty generations. The most reliable work on the development of cancer on gastric ulcer had been done by Hauser of Erlangen. Dr. Hemmeter said he had had the good fortune of seeing the specimens of this pathologist, who claimed that he could always tell whether a carcinoma of the stomach had developed upon the basis of a pre-existing gastric ulcer. Formerly he had always looked upon a penetration of the muscularis mucosa as malignant, but the characteristic described by Hauser was that the muscularis mucosa and the muscular layers from the peritoneum fused, as it were, in front of the carcinomatous mass. Again, there was a characteristic shape; in a vertical section it always presented the shape of a fish-hook The reason was that it was always the lower edge of the ulcer that turned carcinomatous, because this lower edge caught the food and the infectious material, and was subjected to the greatest irritation. He had investigated the behavior of other cells than cancer cells in normal salt solution. This part of the subject had presented many practical difficulties, yet he had not found that the other cells acted in the same manner as the cancer cells. In this connection he desired to say that not all the cancer cells behaved in this way, but that the majority of them did. He had also studied normal cells of the same tissue in expressed cancer juice, and had found that the majority of these cells would contract. He had expected, and, indeed, desired criticism, because this would lead to the attainment of truth.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held February 26, 1903.

L. J. LADINSKI, M.D., CHAIRMAN.

Demonstration of the Automatic Cœliotomy Retractor.—Dr. ARNOLD STURMDORF presented this instrument and said that, in cases of prolonged retraction, the structural shortcomings of retractors in use at the present time became manifest, as was evidenced by the enormous variety of abdominal retractors in vogue. An abdominal incision in a state of retraction presented an opening more or less elliptical in shape and the points of greatest distensibility in this elastic ellipse were in the center of its lateral borders or through its widest diameter. Therefore, to obtain a maximum of opening with a minimum of force the blades of the retractor should be so shaped as to exert the greatest traction on these points of greatest distensibility. With this factor in view, the disadvantage of the usual flat-bladed retractor became evident. Another essential feature of an abdominal retractor was that it should not slip. The retracting surface having been modelled to conform to the outline of the distended incision, two semi-elliptical retraction blades result, which, when placed *in situ*, formed a metallic ellipse, which applied itself snugly to the wound ellipse, thus preventing the possibility of slipping within the wound. The possibility of slipping out of the wound was obviated by a prolongation of the retracting blade, the free end of which was bent outward upon itself, thus enclosing and protecting the whole thickness of the incised abdominal wall. Another requisite was that the retractor should not bruise or lacerate the abdominal incision. He referred to instances of devitalized wound edges, the result of prolonged retraction with improperly shaped retractors. He recalled the prongs, teeth, fenestrations, and other devices with which many retractors were armed. The speculum which he presented was one in which the blades were modified from Fritch and the self-retaining mechanism from Kelly. It did not encumber the operative field or its surroundings. It maintained its position for any length of time automatically. It enabled the operator to alter the lines of traction in any diameter at will without disturbing the operative field. The retaining mechanism was simple and free from unsterilizable crevices and points.

Vaginal Hysterectomy of Gravid Uterus with Carcinoma of Cervix.—Dr. PHILANDER A. HARRIS of Patterson presented this specimen, which he had removed from a woman, thirty-six years old. She had had two or three children. She presented herself to him about one year ago, and stated that she had been bleeding continuously for six weeks and had had spottings of blood prior to that. From the gross appearance he decided that she had cancer of the cervix. The uterus was spherical in form and larger than it should have been and was not lobulated. From other symptoms he judged her to be pregnant. A vaginal operation was performed. Until a few days ago he could have shown the fœtus in the unbroken membranes; the membranes were quite friable and were ruptured in attempts at photographing. He could only recall one other instance of cancer of the cervix with pregnancy existing, although he believed he had had other cases.

Recurrent Tubal Pregnancy.—Dr. PHILANDER A. HARRIS presented this specimen. The patient gave all the evidences of an ectopic gestation, but sections through the mass gave no evidences of chorionic villi, which made the diagnosis doubtful.

The Treatment by Anterior Vaginal Section of Retrodisplacement of the Uterus, Complicated by Adhesions.—Dr. J. RIDDLE GOFFE read this paper and said that operations for the relief of posterior displacements of the uterus were multiform. Theoretically, any operation that possessed any merit must be based upon some mechanical principle that is applicable to the condition under discussion and that follows nature's plan in accomplishing the same end. This necessitated a brief review of the dynamics of the female pelvis and the normal position of the uterus. He said that it was pretty well agreed that the uterus rested upon its anterior face in a condition of unstable equilibrium. The great principle that nature had invoked in retaining the organs of the human body in position was that of suspension by ligaments. Taken weight for weight, there was no organ in the human body that had so many ligaments as the uterus, and it was logical to infer, therefore, that when the uterus had gotten out of its normal position something was wrong with the ligaments, and it was equally as logical to assume that if one wished to restore the uterus to its normal position and maintain it there, the ligaments afforded the proper tissue to utilize for such a purpose. The ligament which served the most important function in supporting the uterus was the sling of tissue, known as the uterosacral ligaments, reaching from the sacrum to the posterior wall of the cervix, plus the uterovesical ligaments, reaching from the anterior wall of the uterus to the symphysis pubis. So long as the uterosacral ligaments retain their proper tone and length, retroversion of the uterus was impossible. It was to some malign influence affecting the uterosacral ligaments that we must look for the cause of retrodisplacement of the uterus, and consequently to the repair or recovery of function in the uterosacral ligaments that we must look for restoration to normal conditions. He believed that undoubtedly the restoration in the uterosacral ligaments might be secured by a direct operation on the ligaments themselves, and while this operation was the most difficult of all to perform, it was a practical procedure, the technique of which could be secured by skill and practice and could be accomplished either through the abdominal or vaginal incision. The next most valuable tissue to utilize for the purpose in hand was the round ligament, which was strong enough to hold the uterus in an antiverted position. When shortened they allow of the normal mobility of the fundus, and at the same time remove the strain from the uterosacral

ligaments to such a degree as to enable the latter to recover their tone. The ultimate result, therefore, was ideal. The objection to the Alexander operation he considered to be its narrow field of application. He said that Wylie and Mann had found the ligaments satisfactory for the work when shortening by the abdominal incision. Olshausen utilized the round ligaments by stitching them into the edges of the abdominal wound. Dührssen, Wertheim, and Vineberg found the round ligaments efficient when stitched to the edges of an anterior vaginal incision. Byford and himself and many others found equally good results by operating through the vagina and doubling the ligaments upon themselves in accordance with the Wylie-Mann suggestion. Then followed a description of the technique of the operation.

During the past six years he had subjected about two hundred cases to this operation. In many of the cases in which retroversion existed there were complications of endometritis, lacerations of cervix and perineum, as well as complicated diseases of the appendages, and it was therefore logical for him to first curette the uterus, repair the lacerations of the cervix, open into the pelvis through the anterior vaginal fornix, break up adhesions, deliver the uterus and its appendages into the vagina, where, within easy reach and in plain sight, such conservative work as was thought necessary was done upon the appendages, shorten the round ligaments, close the vaginal incision, and finally repair the perineum.

Results of Operation.—In his first series of thirty cases there were three or four cases that did not give entirely satisfactory results, but since then his results had been uniformly perfect, not only in relieving the symptoms but in maintaining the uterus in a normal position. It was not enough for the uterus to be held in place; allowance should be made for the function of gestation and parturition. Vaginal fixation and abdominal fixation thwarted the function of the uterus during either of these physiological processes, but not when the round ligaments were utilized for relieving displacements.

How May We Best Reach and Deal with Adhesions that Hold the Uterus in Abnormal Position?—He found no insurmountable obstacle in dealing with adhesions through the anterior vaginal incision, although he did not hesitate to supplement it with a slight posterior incision when the adhesions at the bottom of Douglas' pouch were firm and unyielding. As contrasted with the abdominal route of attack in dealing with extensive adhesions, the vaginal method, which included both the anterior and posterior incision, had the advantage of bringing one at once at the bottom of the cul-de-sac, where it was most advantageous to begin the separation of adhesions. He said that all operators in dealing with adhesions, even in cases of extensive double pyosalpinx, had found that the line of cleavage between diseased structures and the surrounding organs was best followed from below up, and the first effort of the operator was to secure a passage for his fingers at the bottom of Douglas' pouch along the structure that was least likely to be injured. This, as a rule, proved to be the posterior face of the uterus. In all cases in which the uterus and appendages lay within the true pelvis, he said there was no difficulty in reaching and dealing with them safely and efficiently through the vaginal incision. Guided by the sense of touch and sight, he had found no instances in which the adhesions were beyond practicable reach, except in extensive disease of the appendages involving pus. In all cases of retrodisplacement of the uterus, with adhesions, the vaginal incision afforded a safe and efficient means of relief in dealing with the adhesions and, at the same time, offered the simplest and most ideal method of restoring and maintaining the uterus in its normal position. This conclusion was based upon an experience of about two hundred cases, in which it had been found that the operation was absolutely free from danger to life, was devoid of painful convalescence, and left the patient free of any apparent marks upon her body of having been subjected to operation.

Abdominal Section for Adherent Retroversion of the Uterus.—Dr. Egbert H. Grandin read this paper and said that he would not consider the dynamics of the normal positions of the uterus, because the subject under discussion dealt with pathological factors purely and simply. Therefore, it did not matter whether the retrouterine ligaments, or the vesicouterine ligaments, in health maintained the uterus forward, backward, or laterally. He said the subject under discussion was the treatment of *adherent* retroverted uteri; the consideration of the congenitally displaced uterus was out of the scope of the discussion. The retrodisplaced uterus, due to some pathological entity, was what he considered. In considering this subject, he said that we should bear in mind the causal factors that held the uterus backward. The symptoms were not alone dependent upon the unnaturally fixed position of the uterus, but chiefly upon the complications. The principle causal factor was pelvic peritonitis and, back of this condition and responsible for it, was the entrance of some irritating material into the pelvis, which material might come from the tubes, ovaries, appendix, or possibly through the lymphatics or veins; but, no matter where it came from, this irritating material resulted the same, *i.e.* gluing the uterus backward, while the other organs, the tubes, ovaries and appendix, might be distorted in any direction. When the causal actor came from the appendix, he said this organ might become adherent to the tube of ovary; also, the omentum, the sigmoid flexure, the cæcum, and even the small intestines, might become adherent with, or adherent to, the uterus and appendages. The symptomatology of an adherent retroverted uterus was due to the abnormal position of the uterus and adjacent organs interfering with the pelvic circulation. The uterus became enlarged and heavy; the broad ligaments became varicosed; the function of the bladder and rectum were interfered with. Therefore, one was called upon first to tell by the sense of touch just what was present, and, secondly, to apply such measures as would best relieve the symptoms. He said that those who had studied clinically the diseases of women and who had passed through the cycles of multiform treatments, realized the limitations of the sense of touch and were unwilling in a given case to state just how much of a lesion was associated with the adherent retrodisplaced uterus; and, in those cases in which we must bring to the aid of the sense of touch the sense of sight, we were justified in performing abdominal section. With the abdomen opened he said that one could break up the adhesions; if the intestines were injured one could repair the damage. With the abdomen opened one could judge how much work should be done upon the tubes and ovaries and, if deemed necessary, one could remove the appendix through this incision. Also, and this was highly important, one could lift up the sagging uterus and maintain it in a higher position, and thus restore equilibrium of the uterine and periuterine circulation. Sight aided touch, and to attempt to work through the vagina he believed was doing blind work, imperfect work, and far more dangerous work. He did not think one was justified at all in attempting, through the posterior fornix, to break up adhesions, to pull down ovaries and tubes, and to pack in gauze, thus forming new adhesions; by so doing one might injure the intestines or leave in pus-pockets, and ultimately one would be obliged to resort to an abdominal section to repair the injury done. He said that, as the gynecologists became more surgical, the vaginal incision was rarely made except to aid in diagnosis and evacuate pus. He never had attempted to do this work through the anterior fornix, because he had never deemed it at all logical. Besides the extensive mutilation of the vagina it appeared to him more arduous and *blind*. One might as well reach over a fence to pick up some body from the ground when one might reach it readily from under the fence and, in his

opinion, that was what these men were attempting to do when they advocated anterior vaginal incision for retrodisplaced adherent uteri. The uterus was adherent posteriorly, the appendages were glued and the appendix might be adherent to uterus, tubes, or ovaries. Other complications might exist. Yet such operators, under such conditions, make a sagittal and then a longitudinal incision, push up a bladder to which may be attached a pus tube which may be ruptured, and then they carry the hand over the fundus of the uterus and drag it down into the vagina with a diseased tube or ovary or, possibly, appendix. This he did not consider surgery, but butchery, of which even a butcher would be ashamed. As gynecological surgeons, he asked that the alternatives be faced and that we use the sense of sight as well as of touch. He did not believe, with present methods, the vagina could be properly sterilized. During such operations the bacteria coli communis might gain entrance to the wound from the rectum.

Dr. Bache Emmett said that there was merit in the various procedures. The posterior vaginal incision he had only practised for purposes of examination and liberating imprisoned pus; the access was so easy that he had been tempted to proceed further. The anterior vaginal method had given him satisfaction, and every thing that was done was visible. With reference to the argument that no scar was left in the abdominal wall which gave an advantage over the abdominal route, he did not think it was necessary to heed this at all, except in young persons. He thought the anterior method could be selected in a large number of cases. Because sight to him meant something, he preferred the anterior abdominal section in performing operations for retrodisplacements of the uterus. The abdominal route was to be chosen because there might be infected parts that would escape observation of operation was performed per vaginum.

Dr. Frederick Holme Wiggin had had much experience in working through the anterior vaginal incision and believed there were many advantages to be had in this over the abdominal incision. He took issue with Dr. Grandin in his statement that the vagina could not be sterilized. The vagina was very vascular, and wounds there heal readily. He employed no vaginal packing after the operation. At close of such operations he introduced a solution of iodoform in ether 10 per cent., and then placed in a self-retaining catheter in the bladder. For cleansing the vagina he employed the following method: The vagina was douched with a solution of boric acid prior to operation. At the time of operation the vagina and vulva were cleansed with tincture of green soap; this was followed by alcohol, then a bichloride solution in alcohol, 1-300, and then with sterilized water. Where there were many adhesions to deal with, he preferred to go back to the abdominal route. In almost all cases in which the functions of the intestines have been interfered with, and with a chronic appendicitis, if an abdominal section was required, there would also be required a removal of the appendix. In cases with loss of appetite, with no desire for food, but a desire for stimulants, he usually found trouble with the appendix, which was probably secondary to the other conditions.

Dr. Robert A. Murray said that gynecologists should cultivate the sense of touch, but he had never seen an operator who could say absolutely, before opening the abdomen, either by the vaginal or suprapubic route, what he was going to find. Since almost all cases of adhesions around the uterus were due to tubal trouble, frequently pus being present, one should be prepared not only to break up the adhesions, but also to do whatever conservative work was required upon the tubes. He said it had been stated that if one fixed the uterus to the abdominal wall dystocia always followed, yet it was not proven that if the anterior portion of the uterus was drawn up *tight* against the abdominal wall that this would follow. A great many things can be done by the abdominal route that could not be done by the vaginal. The appendages could not be handled so well through the vaginal route. Long after operations by the vaginal route patients have appeared with marked symptoms which were the results of adhesions, some being very serious and some even fatal. He said that in abdominal work, with union by first intention, the resulting scar could hardly be seen.

Dr. S. W. Bandler said he had seen a good many cases operated upon by this method and had spoken in favor of it. He was surprised that Dr. Grandin should take such a decided stand against the vaginal method of work, on the ground that it was unsurgical. Whether the abdominal or vaginal route was the one of choice depended upon the operator. If the vaginal route was a good one, as Dr. Goffe had led them to believe, and if one was able to do it dexterously, he saw no reason why it should not be the route of choice. He had seen and followed two hundred cases. Through the vaginal incision the uterus, tubes, and ovaries could be delivered, cysts opened, and any conservative work done that was deemed necessary. The vaginal incision could be so extended that practically as large an incision could be obtained as was usually made by the abdominal route. He believed the sense of touch was as necessary when working through the abdominal incision as through the vaginal incision. The posterior vaginal incision was a great aid in loosening adhesions. He took exception to the term vaginal fixation; fixation to-day was not really a fixation, but a suspension. Abdominal fixation would cause dystocia; if suspension be made, dystocia would not result.

Dr. A. H. Goelet said that at the last meeting of the American Medical Association displacements of the uterus was considered, and he felt more and more convinced of the wider range of applicability of abdominal section and ventral suspension for this condition of retrodisplaced uteri and the rather limited application of the operation for shortening the round ligaments. He said that Dr. Goffe had very strongly and clearly drawn attention to the uterosacral and uterovesical ligaments as being important factors in maintaining that organ in position, and, therefore, operations for shortening the round ligaments were only applicable when these ligaments were in proper functionating condition, *i.e.* not relaxed. The round ligaments held the uterus forward only. A number of years ago he performed many operations for posterior displacements of the uterus, and he had become convinced that, in uncomplicated cases, in posterior flexions of that organ, there was no relaxation of the uterosacral ligaments. He believed that any operation for shortening the round ligaments had a limited range of usefulness. He referred to two objections to the vaginal route of procedure—(1) the absolute impossibility of sterilizing the vagina by present methods and (2) the anterior vaginal section destroyed the vesicouterine ligaments. If the posterior vaginal incision was also made, the uterosacral ligaments would be destroyed. Therefore, the uterus would continue to sag in the pelvis. Another point he raised in favor of the abdominal route was, where the adhesions of the uterus were very great, the greater facility of dealing with hemorrhages.

Dr. LeRoy Broun agreed with Dr. Grandin and said that all retroverted uteri were not always associated with pyosalpinx. When the adhesions were dense, he preferred to open the abdomen; if they were not dense, he preferred to work through the vagina.

Dr. Philander A. Harris said that the greatest prejudice arose from those who did not do much work of this kind, or, if they did, who did not make themselves familiar with the technique.

Dr. Arnold Sturmdorf said that if he could do as well as Dr. Goffe he would prefer the vaginal section.

Dr. L. J. Ladinski said that the subject under discussion was the choice of route in performing operations for retrodisplaced uteri and, it seemed to him, that those who

favored the abdominal route preferred to do ventral suspension, and those who preferred the vaginal route favored vaginal suspension or shortening the round ligaments. Personally, he advocated the vaginal route, and his results and experience would not justify him in changing his route of preference.

Dr. J. Riddle Goffe argued that the vagina could be sterilized as well as the skin could. He said it might be claimed that the abdomen could not be sterilized because you met with stitch-hole abscesses. Occasionally, in the vagina, he found evidences of infection; but it was rare. Working through the vagina was not working in the dark; one could see as well the field of operation as though working through the abdominal incision. With regard to dyspareunia following incision into the vagina, he had never seen an instance resulting from the scar that had formed. In the case reported by Dr. Wells it followed the posterior, and not the anterior, vaginal incision. He had had ten pregnancies following his vaginal work, and every one of them had gone through gestation with comfort and through parturition without untoward results.

Dr. A. Reich referred to two cases that had been operated upon by the vaginal route for retrodisplacement of the uterus. Neither of them had any trouble at all during gestation or parturition, and the uteri remained in perfect position.

Drs. Moffat and Hermance of Yonkers were present and added their testimony to the advantages of the vaginal over the abdominal route in operation for retroverted uteri.

Cancer among Negroes.—At the Egyptian Medical Congress, January 15, 1903, Dr. Legrand of Alexandria reported a case and exhibited a photograph of a negress whose breast he had amputated for scirrhous cancer, proving that there exist still, though very rarely, isolated cases among the black races.—*Journal of Tropical Medicine.*

Physical Degeneracy from Environment.—Ivar Janson has made a study of effects of the change of environment on the peasant class from Norway, the change including atmospheric conditions, dirt, and drinking water. We observe first a loss in the buoyancy of bodily poise; the elasticity of the gait is changed to clumsiness; the people seem out of place. The lustre of the hair disappears and gives way to a dryness, followed by falling out. Often digestive disturbances supervene, and constipation becomes very common. This is especially the case among young girls and women, and in their train we get congestion, and toxæmic maladies, anæmia, displacements of the womb, dysmenorrhœa, etc. If these people are young, they become, in a much higher degree than formerly, receptive to the contagion of tuberculosis, and if older, rheumatism becomes prevalent. In this same generation of peoples who have been transplanted into different life conditions and who, on account of pre-existing conditions of sameness, have not yet acquired the toleration necessary to flourish in this new life, we also frequently find a breaking down of the nervous system. In the hospitals for the insane the proportion of Scandinavians is quite appalling, also of German, Swiss and allied peoples. Sometimes we may get the opposite effect, of the same stimulus applied, namely, the kindling into activity of potential mental energies. And from the simple peasant lads we derive acute financiers, politicians who come to the front, great professionals and talented devotees in the various branches of art. This mental activity, however, does not prevent physical decay or degeneration, and often a brilliant career is cut short by tuberculosis, cancer, premature fibrosis, etc. The children of these transplanted people show increased rec ptivity to disease, especially tuberculosis.—*Northwest Medicine.*

Book Reviews.

A Textbook of Clinical Medicine. Principles of Diagnosis. By Clarence Bartlett, M.D., Professor of Clinical Medicine and Associate Professor of Medicine in the Hahnemann Medical College of Philadelphia; Senior Neurologist to the Hahnemann Hospital, etc. With 245 Illustrations, Including Six Colored Plates. Philadelphia: Boericke & Tafel, 1903.

This work includes nearly a thousand pages of condensed facts relating to the clinical interpretation of symptoms. At the beginning the author makes a plea for the careful examination of patients, and the avoidance of slipshod methods which so often favor errors of diagnosis. The outlines of general and special interrogation are given, and are followed by descriptions of the diagnostic points in temperature, pulse, and respiration records. Special chapters are given to the thoracic and abdominal organs, the nose, throat, and larynx, the blood and nervous system, the eye and ear, and a concluding section on *x*-ray diagnosis. The work covers the ground of the more common and many of the uncommon diseases met in the practice of internal medicine, and there has been a wise selection of illustrations, which are particularly numerous.

A Textbook of Nursing. By Clara Weeks-Shaw. Third Edition. New York: D. Appleton & Co., 1902.

This excellent textbook richly deserves the reputation it has already won. The author's good common sense and judgment, and her high conception of the profession of nursing everywhere pervade her writings, and add emphasis to one of the precepts laid down in the introduction, viz.: That the degree of harmony which a nurse is able to maintain with all the members of a family is more convincing evidence of her good sense and fitness for her position than the most brilliant examination papers. Would that every reader would heed the injunction "that a well-disciplined nurse never makes a diagnosis and never prescribes!" While heartily commending the work in its entirety, as a complete and reliable guide for nurses, we cannot see the wisdom of trying to give them that little knowledge of urinary analysis which is only too apt to prove dangerous rather than helpful.

The Nursing Profession; How and Where to Train. By Sir Henry Burdett, K.C.B. London: The Scientific Press, Limited.

The author is widely known as an indefatigable writer and organizer in the hospital world. Although this is the fourth year of this publication, it has hitherto been issued as a part of the author's "Official Nursing Directory." It contains a vast amount of up-to-date and official information concerning nurse training schools in England and its colonies, which should prove of value to those desirous of becoming nurses as well as to officials of these schools, who are besieged with requests for just such detailed information. Only typical nursing institutions in the United States have been considered.

Obstetrical Nursing for Nurses and Students. By Henry Enos Tuley, M.D., Professor of Obstetrics, Kentucky University; Visiting Obstetrician to the John N. Norton Memorial Infirmary, Louisville City Hospital and the Home for Friendless Women. Chicago: G. P. Engelhard & Co., 1902.

This book is an elaboration of the author's lectures in obstetrics at the institutions with which he is connected. The teaching throughout is sound and practical, and reflects the latest and best opinions of obstetricians. There is little to criticise, yet we cannot help feeling that it is wholly unnecessary, and, indeed, undesirable, to devote a whole chapter to the detailed instruction of nurses in the diagnosis of pregnancy. The home modification of milk very properly receives due consideration. The author's remarks on the personal preparation of the mother's food by the nurse, the ease with which the new-born infant acquires bad habits, and the significance of the infant's peculiar language—crying—are worthy of special commendation.

A Manual of Otology. By Gorham Bacon, A.B., M.D. Philadelphia: Lea Brothers & Co., 1902.

The necessity of a third edition of this manual within four years of its first appearance shows the value placed upon the book by the medical public. A number of original illustrations have been added in this edition.

Schwabach's important test, not mentioned in former editions, is described, the importance of a thorough incision in the drum membrane in cases of acute purulent otitis media is mentioned, and the use of anæsthesia in its performance is most justly urged. On page 256 the author reports a new case to prove that tubercle bacilli are at times the cause of a chronic purulent otitis media. On page 299 are enumerated seventeen paths of communication between the ear and the cerebrospinal system, by means

of which septic material or septic organisms may find their way from the former to the latter. The practitioner who considers a discharging ear a very insignificant affair should have his attention called to this fact.

That aural surgery is rapidly gaining the importance it is entitled to in the community is well shown by the statement that in the New York Eye and Ear Infirmary the number of mastoid cases operated upon (and this included cases with cranial and other complications) increased from 167 in 1897 to 271 in 1901.

On page 316 the important fact is stated that a bacteriological examination of the aural discharge will enable the surgeon to determine the necessity or non-necessity of operative interference in obscure cases. Again, on page 328, the author makes a plea for the constant attendance of the aurist upon a case of mastoiditis, so that he may, at a moment's notice, operate if more conservative measures are not of use, and so prevent a possible intracranial complication. The author's description of the spina suprameatum, on page 334, as a guide to the antrum, is not sufficiently explicit to be easily understood by the beginner in Otology. As an additional aid to a diagnosis of a possible brain abscess, it is urged, on page 365, that the presence or absence of a leucocytosis be determined. Other matter adds twenty pages to this edition, and gives it a still greater value than that possessed by former editions.

The Physician's Visiting List for 1903. Philadelphia: P. Blakiston's Son & Co.

A publication which has reached its fifty-second year surely needs but little comment. Suffice it to say that the success implied in this long and honorable record is dependent chiefly upon the simplicity, adaptability, and compactness of this list. In addition to the space for accounts, there are useful memoranda with regard to the incompatibility of drugs, the treatment of cases of poisoning, and tables of weights and measures with a comparison of thermometric scales.

Uricacidæmia; Its Causes, Effects, and Treatment. By Perry Dickie, M.D. Philadelphia: Boericke & Tafel, 1903.

While there is no great demand at the present time for books which, like this one, only claim to be a convenient epitome of the well-known theories of Haig, still the work might have proved acceptable to a certain number of physicians were it not that the author's style is so involved, and the construction of his sentences so faulty that it is only by an unpleasant effort that the reader is able fully to grasp his meaning. These faults have been intensified by the fact that the proof-reading has been wretchedly done. The chapters on diet and hygiene are not without merit, so that it is particularly unfortunate that the author's thoughts should have been so unworthily clothed.

The Practical Medicine Series of Year Books. Vol. III. The Eye, Ear, Nose, and Throat. By Casey A. Wood, M.D., Albert H. Andrews, M.D., and T. Melville Hardy, M.D. Chicago: The Year Book Publishers, 1902.

In this publication the portion devoted to the eye is edited by Dr. Wood; that to the ear by Dr. Andrews, and that to the nose and throat by Dr. Hardy. Taken as a whole, the volume is a decided improvement on the corresponding volume of last year's series. It is printed on better paper, more systematically arranged, and has a better index. Practically all the important matters of the year receive mention, and to one who does not follow the special journals from month to month the book will serve as a sufficiently thorough review. A few illustrations are scattered through the pages, but they are not of any special excellence. If medical books are to be illustrated at all, no pains should be spared to make such illustrations the best possible.

Book on the Physician Himself and Things That Concern His Reputation and Success. By D. W. Cathell. Twentieth Century Edition, Revised and Enlarged by Author and His Son, Wm. T. Cathell, A.M., M.D., Baltimore, Md. 8vo, pp. 403. Philadelphia: F. A. Davis Co., 1902.

More than a score of years ago the Physician Himself took its stand as a helpful guide to the medical man in his relations with his profession and the public. It was the plain talk to the reader on what he should do and not do in order to insure his success in his calling. The attention given to little things bearing on his purely personal side was the distinguishing feature of the work and commanded for it a wide reading. In the present edition the volume has been much enlarged and brought up to present-day requirements. While many of the injunctions regarding dignified behavior, gentlemanly conduct, fair dealing with brother practitioners, and the like would be taken for granted, there is still need for the practical interpretation of those principles of ethics which lie at the foundation of all real success in practice. To the young man commencing practice the lessons in etiquette will be found to be of greatest value in helping him to to decide doubtful points in ethics and in enabling him to avoid many serious misunderstandings with his patients and *confrères*.

Therapeutics of Dry Hot Air. By Clarence Edward Skinner, M.D., LL.D., Professor of Thermotherapy in the New York School of Physical Therapeutics. Editor of the Department of Thermotherapy in the Journal of Advanced Therapeutics; Physician in Charge of the Newhope Hot Air Sanatarium, New Haven, Conn., etc. New York: A. L. Chatterton & Co., 1903.

This author gives a great deal of attention to what is at present a rather obscure and unimportant therapeutic possibility. The tone throughout the abstract general portions is very conservative and reasonable, but, in the treatment of the different diseases, is rather sanguine. Although the author disclaims, in the preface, that dry hot air is a universal panacea, a perusal of the volume rather gives the impression that he believes it is. The book will appeal to those who have large sanataria and extensive apparatus at their disposal, and who are inclined to experiment rather than to the average physician.

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Chirurgie Intestinale d'Urgence. Par Albert Mouchet. 12mo, 95 pages. Illustrated. J. B. Bailliere et Fils. Paris, Price, Fr. 1.50.

Clinical Treatises on the Pathology and Therapy of Disorders of Metabolism and Nutrition. By Dr. Carl von Noorden. 8vo, 59 pages. E. B. Treat & Co., New York. Part I, Obesity. Price, 50c. Part II, Nephritis. Price, $1.00.

Obstetrics: A Text-book for the Use of Students and Practitioners. By J. Whitridge Williams. 8vo, 845 pages. Illustrated. D. Appleton & Co., New York.

Manual of Bacteriology. By Robt. Muir, M.D., and James Ritchie, M.D. 8vo, 565 pages. Illustrated. The Macmillan Co., New York.

Therapeutics of Infancy and Childhood. By A. Jacobi, M.D. 8vo. Third Edition. 560 pages. L. B. Lippincott Co., Philadelphia. Price, $3.50.

The American Year-book of Medicine and Surgery. By George M. Gould and others. 8vo, 671 pages. Illustrated. W. B. Saunders & Co., New York. Price, cloth, $3.00; half morocco, $3.75, net.

The Anatomy of the Human Peritoneum and Abdominal Cavity. By George S. Huntington, M.D. 4to, 292 pages. Illustrated. Lea Brothers & Co., Philadelphia. Price, $10 net.

The Prize Essay on the Erection of a Sanatorium for the Treatment of Tuberculosis in England. By Arthur Latham, M.D. 8vo, 254 pages. Illustrated. Bailliere, Tindall & Cox, London.

A Compend of Diseases of Children. By Marcus P. Hatfield, M.D. 16mo, 241 pages. Third edition. P. Blakiston's Son & Co., Philadelphia, Pa.

Cours de Mineralogie Biologique. 16mo, 363 pages. By J. Gaube. A. Maloine, Paris. Price, Fr. 4.

The Medical Epitome Series, Physiology. 12mo. By Theo. C. Guenther, M.D., and others. 255 pages. Illustrated. Lea Brothers & Co., New York. Price, $1.00 net.

Transactions of the American Orthopedic Association, Sixteenth Session. Vol. XV, 8vo, 216 pages. Illustrated. By the Association, Philadelphia.

International Clinics. By Henry W. Cattell, M.D. Vol. IV, Twelfth Series. 8vo, 317 pages. Illustrated. J. B. Lippincott Co., Philadelphia, Pa.

The Life Within. 12mo, 385 pages. Lothrop Publishing Co., Boston

The Practical Treatment of Stammering and Stuttering. By George Andrew Lewis. 16mo, 415 pages. Illustrated. Detroit, Mich.

Experiments on Animals. By Stephen Paget. 8vo, 387 pages. C. P. Putnam's Sons, New York.

The Medical Epitome Series, Obstetrics. By W. P. Manton, M.D. 12mo, 265 pages. Illustrated. Lea Brothers & Co. Price, $1 00.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending March 7, 1903:

	Cases.	Deaths.
Measles	225	6
Diphtheria and croup	376	42
Scarlet fever	266	19
Smallpox	..	..
Varicella	147	..
Tuberculosis	303	169
Typhoid fever	46	8
Cerebro-spinal meningitis	..	..

The Results of the Experimental Exclusion of the Motor Function.—M. Rothmann considers the pathological significance of the results of the experimental and clinical studies which have been made on the exclusion of the motor tracts in animals and man. These show that, in the main, the motor function has very great powers of restitution and can stand serious injury without permanent damage. Experimental work on all the higher mammals up to the monkey shows that the pyramidal tracts are not the only conducting paths for the motor impulse, and that their bilateral destruction does not induce serious paralytic manifestations of any permanence. Even including the monkey, the power of restitution is so perfect that the destruction of all the motor tracts of one side of the cord does not induce lasting paralysis. These observations, taken in conjunction with clinical studies in cases in which the intra- and extrapyramidal motor fibers have been diseased show that the acute destruction of the pyramidal tract only, leaving the other motor fibers intact leads to a paresis of the extremities in question which has not yet been found to disappear completely. Acute destruction of the pyramidal tract and the other conducting tracts in the internal capsule or in one side of the cord produces flaccid paralysis of the extremities which after some weeks undergoes incomplete restitution. Even in complete division of one-half of the cord the originally paralyzed leg becomes useful for walking again. The rare, very chronic, cases, described as pure spinal spastic palsy, in which both pyramidal tracts are diseased without lesions of any other portion of the cord ran a course without true paralysis. The hypertonicity of the muscles of the legs which is constantly observed cannot be ascribed to the disease of the pyramidal tracts, since it may be absent in lesions of the lateral columns and may be observed without them. Therefore the only permanent symptom of the exclusion of the pyramidal tracts is the exaggeration of the tendon reflexes. Unilateral lesions of the medulla, on the other hand, show that the pyramidal tract alone is able to continue the motor functions perfectly without any assistance from the other motor tracts. The clinical studies, therefore, correspond closely with the results of animal experimentation, though the pyramidal tract possesses a more important relation to the motor function in man than in animals, and its loss is compensated for but slowly. Still the power of restitution is scarcely less in man than in the higher mammals, though influenced to some extent by his upright posture.—*Zeitschrift für klinische Medicin.*

The Prosthetic Use of Hard and Soft Paraffin.—Gersuny adds several hints to his former communications on the use of paraffin injected under the skin and into the cellular tissues of various regions of the body for the purpose of repairing defects. In discussing the suggestion that has been made to using a paraffin of a higher melting point than 35–40° C., the variety employed by himself, the author says that this does not seem to offer any material advantages. The greater freedom from the risk of embolism which is claimed probably does not exist since the material, at the time of injection at least, is fluid, while the technical difficulties of its introduction under the skin are greater. The assertion made by some that the softer paraffin might become liquified in the event of the patient's bodily temperature rising during some febrile disease rests upon a mistaken idea of the effect of the injection. The material does not remain in the tissues simply as a mass surrounded by a connective tissue capsule, but is permeated in all directions by a new growth of connective tissue trabeculæ, which divide and subdivide it into minute droplets, and it is this connective tissue and not the paraffin itself which gives the prosthesis its firmness and permanence. The formation of emboli may be guarded against by the precaution of first injecting a few drops of cocaine or Schleich's solution. The syringe is removed from the needle and the non-appearance of blood from the butt of the needle indicates that no vein has been injured and the paraffin syringe may be applied and the injection proceeded with. The author designates as "hard" injections of paraffin which has a melting point higher than 35° C., and describes a mixture intended for use in cases in which a softer material is required. This consists of one part of paraffin to four parts of olive oil by volume. When this is used the olive oil undergoes gradual absorption and leaves the paraffin behind diffused through the tissues in a highly subdivided state. Cases in which this mixture was successfully used include facial hemiatrophy, smallpox pitting, pigmentation of the skin and the difference of color and level resulting from Thiersch skin grafting.—*Centralblatt für Chirurgie.*

The Endothelial Phagocytes of the Tonsillar Ring.—J. L. Goodale finds that in the normal tonsils large mononuclear phagocytes are present which appear to be derived from a proliferation of the endothelial cells of the reticulum. In hyperplasia of the tonsils there is a proportionate increase in the proliferation of the endothelial cells of the reticulum, and formation of phagocytes, without, however, a corresponding increase in the number of lymphoid cells, or in the endothelial cells of the blood vessels. In atrophy of the tonsils, the endothelial cells of the follicles are seen first to diminish in number, and endothelial phagocytes are correspondingly few, while the lymphoid cells persist relatively longer. In acute inflammation, the characteristic feature of the process consists of a heightened proliferation of the endothelial cells of the blood vessels, with swelling of their cytoplasm, together with an increased number of lymphoid cells. These changes are relatively more marked than the increased endothelial proliferation of the reticulum with follicles. When circumscribed abscess formation occurs in the follicles, an increased proliferation of the endothelial cells, both of the reticulum and the capillaries, is observable in the vicinity. When an intense irritant acts upon the endothelial cells of the tonsil, degeneration and necrosis result in the immediate vicinity. At a greater distance proliferation appears to be excited in these cells. It seems, therefore, probable that proliferation of the endothelial cells of the reticulum with a formation of phagocytes, is not necessarily dependent upon the influence of bacterial toxins for its production, but appears rather to stand in a definite relation to the size of activity of the organs in question. Proliferation, on the other hand, of the endothelial cells of the blood vessels was found to occur only in association with other phenomena of inflammation.—*Annals of Otology, Rhinology, and Laryngology.*

The Pathology and Diagnosis of Otitis Media Insidiosa (Sclerosis), with Remarks on Treatment.—H. J. Hartz offers the following conclusions: (1) Sclerosis is fundamentally a hyperplasia of the bony capsule of the labyrinth; the hyperplasia is a transformation of cartilage into bone, *i. e.* metaplasia, accompanied by formation of outgrowth of bone, *i. e.* hyperostosis. (2) It is initiated

by constitutional diathesis, such as inflammatory rheumatism, gout, syphilis, and scrofula, by diseased tonsils in the pharynx and vault, suppurations with calcareous deposits in the tympanic cavity, exposure to cold and wet and injury. (3) Its localization is usually in the labyrinth capsule near the stapes articulation with the oval window, inducing fixation of the ossicles. (4) It may involve also the semi-circular canals and cochlea, to produce symptoms of nervous deafness. (5) It may affect simultaneously the sound conduction and the sound perception apparatus. (6) The functional test, the subjective symptoms, and family history permit an early diagnosis of this disease. These are: hyperæmia of promontory, heredity, prolonged bone conduction (Schwabach's test) negative Rinné in varying degree and defective perception of one-half to one and one-half octaves of the lower tones. (7) Probably 10 per cent. of the middle-ear diseases are true sclerosis and are designated synonymously capsulitis labyrinthi, otosclerosis, spongification, dry middle ear, catarrh, and otitis media insidiosa. The therapy is effective in early stages of the disease by hygienic and medicinal treatment. The more advanced cases may be improved by judicious treatment with amelioration of tinnitus.—*Annals of Otology, Rhinology, and Laryngology.*

A Case of Acute Osteomyelitis, with Remarks on the Surgical Treatment of This Affection.—Charles Greene Cumston, after describing a case of acute osteomyelitis of the leg, in which operation brought relief, says that trephining the bone in moderately severe cases is the proper treatment to select, but when the disease takes on an excessively malignant aspect, resection of the diseased bone or amputation of the limb will have to be resorted to. Immediate resection of the diseased bone must be resorted to in the acute cases in which there is complete detachment of the periosteum from the entire bone, in acute osteomyelitis of the bones of the skull, in cases of hyperostosis accompanied by suppuration and necrosis arising from a chronic osteomyelitis, and in those cases of neuralgic osteitis, when after trephining the bone the pain still remains acute. Early resection should be performed in all cases of osteomyelitis when trephining the bone and curettement of the abscess have proved insufficient. Late resection is indicated when there are invaginated sequestra in the newly formed layers of bone, which jeopardize the patient's life on account of the prolonged suppuration which has been kept up by their presence. The periosteal layer must be preserved in resections of the diaphysis, while the periosteal capsular canal must not be encroached upon in resection of the joint. Resection is especially indicated in childhood and adolescence, because during this time of life the osteogenic properties of the periosteum are marked, but nevertheless, in certain cases it has been practised successfully in the adult.—*Pediatrics.*

The Pathogenesis of Intermittent Hydronephrosis.—M. P. Bazy concludes that this affection is due to a congenital formation of the pelvis of the kidney, and accessorily of the ureter. A large pelvis of a horizontal type, sharply bent or shaped like a bagpipe, is the condition most apt to produce hydronephrosis; it is extremely rare, but so also is intermittent hydronephrosis. Accessory conditions in the production of this affection are, narrowing, folding, or torsion of the upper part of the ureter. Movable kidney may cause the disease, but the author is inclined to think that ptosis and mobility are more apt to be the consequences than the cause. Hydronephrosis is caused by the stagnation of a small amount of urine in a congenitally voluminous pelvis, congenitally so formed as to permit this stagnation from the slightest cause. By constant repetition of the cause, the stagnation becomes more and more marked, until the kidney falls from its own weight, and thus causes another condition favorable to stagnation, the ptosis inducing a crisis of intermittent hydronephrosis. Adhesions may form and convert the condition from an intermittent to a permanent one.—*Revue de Chirurgie.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ending March 7, 1903:

THE PRESENT STATUS OF THE X-RAY TREATMENT OF MALIGNANT TUMORS.*

BY WILLIAM B. COLEY, M.D.,
NEW YORK.

SURGEON TO THE GENERAL MEMORIAL HOSPITAL; ASSOCIATE SURGEON TO THE HOSPITAL FOR RUPTURED AND CRIPPLED.

THIS subject, while a comparatively new one, has assumed front rank in the amount of interest it has aroused among both the profession and the laity. Cancer in the broad and, I think, proper sense, including all the varieties of malignant tumors, is unquestionably on the increase, while our means of combating it have, up to the present time, failed to keep pace with this increase. Hence, it is no wonder that we are ready to grasp any new means of curing it or of rendering its victims more comfortable. It is strange that while the *x*-ray has been used for six years or more, and while numerous cases of superficial epithelioma have, from time to time, been reported as having disappeared under its influence, that, up to very recently, no serious attempts have been made in a systematic way, to test its value in al varieties of malignant tumors.

To Dr. J. E. Gilman of Chicago and Dr. Carl Beck of New York must be given the credit of being among the pioneers in advocating the *x*-ray in the more deeply seated forms of cancer. In a paper presented before the Clinical Society of Chicago, December 29, 1900, entitled "The *x*-Ray in Carcinoma' Gilman stated that he had "treated twenty-five cases of true cancer and allied troubles with a loss of only two cases, one of them an epithelioma of the throat and another a scirrhus of the left breast." In this paper he gave an account of an extensive inoperable carcinoma of the breast, treated in June, 1900, with very great improvement. Of course, none of these cases had remained well sufficiently long to be called a cure. Yet, the remarkable results which Gilman claims to have obtained, though received with a great deal of skepticism, undoubtedly did much toward arousing interest in the subject.

Gilman, in his latest paper on "The Treatment of Malignant Neoplasms with the *x*-ray" (*North American Journal of Homeopathy*, January, 1903), makes the following statement: "I have at present over 100 cases of the various forms of the cancer family under treatment and observation. I have within the past four years treated over 200 cases of which I have the results, with a record of recoveries somewhat greater than the average recoveries from typhoid fever in ordinary practice."

After making this general statement, without any detailed report of the cases, without the mention of a single case in which the disease entirely disappeared and the patient remained well sufficiently long to justify one in regarding it as a cure, he concludes that "we have arrived at a stage of rational treatment which will reduce the mortality of cancer to an insignificant factor." He even goes on so far as to state that excepting recurrent and far advanced cases in which generalization has occurred, "not 1 per cent. is lost.

On May 6, 1901, Dr. Carl Beck showed before the German Medical Society of the City of New York, a case of recurrent melanotic sarcoma of the leg, treated in the early part of 1901, by means of the *x*-rays, with exposures varying from ten to forty-five minutes, with the remarkable result that a local recurrence about the ankle entirely disappeared, together with a number of metastatic tumors of the groin. The case, however, was too far gone and later continued to progress, causing death in the latter part of the year.

Dr. Francis Williams of Boston, in his well-known book upon the *x*-ray and in his later monographs, has given abundant evidence that superficial epitheliomas may be made to disappear under the *x*-ray treatment.

Pusey and Grubbé of Chicago, Skinner of New Haven, and Morton and Johnson of New York, not only confirm the statements of Williams as regards epithelioma, but have also shown that the larger and more deeply seated growths, for example, sarcoma of the neck, and recurrent carcinomas of the breast, may likewise disappear under similar treatment.

Pusey states that "the definite effect of the *x*-ray on sarcoma is demonstrated as conclusively as a demonstration can be made in medicine. It is impossible to believe the disappearance of this sarcoma was simply a coincidence with the exposures to the *x*-ray. At the time the treatment was begun, the tumor was growing rapidly and its subsidence was *pari passu* with the accumulation of the effects of the rays. The patient had no concurrent disease and no other treatment."

Pusey believes that in cases of sarcoma which cannot without any risk be treated successfully by surgical means, the effect of the *x*-ray should be tried. He further believes that cases of sarcoma which have been operated upon should have the *x*-rays subsequently used as a prophylactic measure against recurrence.

Pusey further reported two remarkable cases of Hodgkin's disease treated with the *x*-ray, showing marvelous improvement.

In a later report* Pusey gives a detailed account of his cases treated with the *x*-rays up to date. There were eight cases of epithelioma of the face and nose; six cases of carcinoma of the breast; six of deep-seated carcinoma of the neck and head; four of carcinoma of the abdominal cavity, and three cases of sarcoma.

Some of Pusey's cases, especially those of cancer of the breast are worthy of note.

CASE I—Female, aged forty-eight years. Re-

*Read before the New York Surgical Society, November 17, 1902; the subsequent histories of the cases, however, are given up to January, 1903.

**Journal of the American Medical Association*, April 12, 1902.

current carcinoma of the breast. There was a large carcinomatous mass at the site of the scar with much œdema of the arm. At the end of four months' treatment, all nodules had disappeared. The case is illustrated by photograph before and after treatment.

Case II—Female, aged fifty-eight years. Recurrent carcinoma of the breast, pronounced inoperable by Fenger. Pusey states that one square foot of cancer area was present, with an ulcerated portion of two by three inches. The treatment was begun in November, 1901, and after two and one-half months the disease had entirely disappeared. A photograph before and after treatment was published.

Case III—Female, aged forty-nine years. Recurrent cancer of the breast. Treatment was begun in October, 1901. After two and one-half months entire disappearance, confirmed by Dr. Ochsner of Chicago.

Pusey states that in three other cases of carcinoma of the breast the *x*-ray treatment had little if any effect upon the disease, the treatment being continued in one case for sixty-six sittings.

Wallace, in Washington (*American Medicine*, August 9, 1902), reports five cases of cancer of the breast treated with the *x*-ray, all of which were discharged without improvement.

One of the most important of the early cases of sarcoma treated with the *x*-ray is that of Dr. E. R. Fiske of Brooklyn. The patient, Mr. H——, seventy-one years of age, had been previously operated upon six times at the New York Hospital, for recurrent, round-celled sarcoma of the neck. He was under my care at the General Memorial Hospital in June and July, 1901, being treated with the erysipelas toxins, without success. In addition his external carotid artery was tied, with no apparent influence upon the progress of the growth. He left the hospital with a large inoperable tumor involving the cervical and mastoid regions. The growth continued to increase in size until December, 1901, when the *x*-ray treatment was begun by Dr. Fiske. At the end of six weeks' treatment the growth had entirely disappeared. With Dr. Fiske's permission I exhibited the patient at the New York Academy of Medicine in March, 1902, no trace of the disease being present at that time. He subsequently developed metastatic tumors in the axilla and both groins, which, however, also yielded to the *x*-ray treatment.

A letter from Dr. Fiske, dated January 23, 1903, states that the patient is still free from recurrence.

The case is of extraordinary interest inasmuch as the character of the growth had been determined by repeated examinations at the laboratory of the New York Hospital. All the old sections were again carefully examined by Dr. Geo. P. Biggs of the New York Hospital and myself, and the diagnosis of small round-celled sarcoma was beyond question.

Skinner of New Haven, who has had a large experience with the *x*-ray in malignant tumors, has recently reported his results in the *Journal of Advanced Therapeutics* (October, 1902.) He has treated thirty-three cases, which he divides in the following way: (1) Those which ended fatally; (2) those in which bony tissue was involved; (3) abdominal cases; (4) mammary cancer; (5) sarcoma, of which variety he has had two cases only.

The results were as follows: Complete disappearance of the disease in three cases; permanent reduction of the tumor in thirteen; temporary reduction with subsequent increase in one; permanent arrest only of growth in twelve. There was no effect positively demonstrated upon the size of the lesions in fourteen.

As regards pain, permanent relief was secured in fourteen; complete temporary relief in two; partial relief in eight; no relief whatever in four; and in five the original growth was not accompanied by pain.

Skinner states that the general condition of the patients was permanently improved in eleven; temporarily improved in eight; not improved at all in eight; and in six the general condition was not noticeably impaired at the time the treatment was begun.

Gain in weight was observed in six; no increase was apparent in twenty-seven.

In nine cases in which there had been hemorrhage, the latter was lessened in eight and not influenced in one.

There were evidences of systemic toxæmia in fourteen cases.

In five cases there was no apparent evidence of benefit, but of these five three received only two or three treatments. Of the three cases in which the tumors had disappeared, in none had a year elapsed.

At the discussion on the value of the *x*-ray in cancer, at the British Medical Association (*British Medical Journal*, October 25, 1902), Dr. Sequeira of London states that of eighty cases of rodent ulcer treated at the London Hospital thirty-four were entirely healed and the majority of the rest were still under treatment. Some cases had small recurrences, but these were easily treated; while in others there had been sound health and absolute freedom from the smallest recurrence for two years. He states that microscopical examination of the tissues treated showed that the rays have two definite effects—first, the epithelial cells are destroyed, nucleus and protoplasm undergoing lysis; in some cells there was a definite fatty change. The second change was a stimulation of connective tissue elements, causing formation of healthy scar tissue. His experience, showing that glandular affections of epitheilomatous origin were exceedingly obstinate to the action of the rays, is in entire keeping with my own. I have treated one case of recurrent epithelioma of the tongue forming an extensive glandular infiltration of the entire submaxillary and cervical region for three months with the *x*-ray with little or no improvement. Another case of extensive primary epithelioma of the neck, involving the submaxillary glands on both sides, has already had three months' treatment with no effect as regards retarding the progress of the disease.

At the same time with this latter case, there was being treated one with a large epitheliomatous growth behind the ear, not involving the glands, which was very much improved for a time, but finally the treatment lost its effect.

At the meeting of the Edinburgh Medical and Chirurgical Society, on November 5, 1902, Dr. Dawson Turner reported eighteen cases of various forms of cancer which he had treated with the *x*-ray. Nine of these were cancer of the breast, two of the tongue, one of the scalp, one of the cervix, one of the rectum, one of the glands of the groin, one probable sarcoma of the neck. All of these cases were inoperable. Turner states that all but three showed more or less improvement, and in some cases improvement was most remarkable. According to his experience, the best results were seen

in recurrent cancer of the breast and the poorest results in cancer of the tongue. He further states that in no case has there been a definite cure, and that recurrence after disappearance has been generally observed.

Grubbe of Chicago (MEDICAL RECORD, November 1, 1902), reports some remarkable cases of cancer of the breast treated by the *x*-ray.

CASE I—Recurrent cancer of the breast after three operations. Examination reveals a large area of disease with a small skin infiltration, the size of a pea. Gradual disappearance of the nodules under four months' treatment. Improvement in general health.

CASE II—Female, aged forty-eight years. Scirrhous cancer of the right breast, recurrent after operation. Entire disappearance under less than five months' treatment.

CASE III—Inoperable cancer of the left breast, presenting an ulcerated area of seven by five and one-half inches. Twenty minutes' treatment, every other day for three months. Entire disappearance. No recurrence at the end of one year.

CASE IV—Recurrent, inoperable cancer of the uterus. The condition was so desperate that the prediction of death within a month was made. The treatment was begun in May, 1901. At the end of two months the patient had gained twenty-two pounds in weight, the pain had disappeared and the foul discharge had almost entirely ceased. After an additional three months she was discharged "symptomatically cured." At the end of eleven months she had gained thirty-five pounds in weight, and states that she is perfectly well.

At the recent *x*-ray symposium of the New York State Medical Association, Dr. Charles W. Allen (MEDICAL RECORD, November 15, 1902), reported fifty cases of cancer treated with the *x*-ray during the current year. A large proportion of these cases, however (thirty-three), were superficial epithelioma of the rodent ulcer type or other forms of cutaneous carcinoma. Ten cases were mammary cancer; seven recurrent, and three primary. Of this number he states that twenty-six, or 52 per cent., were discharged "clinically cured." Three only were discharged unimproved; five ended fatally.

All of these cases having been treated during the last year, it is, of course, impossible to regard any of them as actually cured. At the same time, the mere disappearance of undoubtedly malignant disease in this large proportion of cases is a fact of very great importance.

The use of the *x*-ray in primary cancer of the breast before, or in preference to, surgical intervention is advocated by Dr. Allen on the ground that there is a very large class of patients who will reject surgical treatment and will never submit to it.

Personally, I do not believe that this class is very numerous. In my own experience I have never met with more than two or three individuals who, after a careful setting forth of the facts, refused to submit to operation for cancer of the breast. This small class of cases, I believe, should have the benefit of the *x*-ray treatment. At the same time, I consider it to be extremely unwise for the laity to become possessed of the idea that in the *x*-ray we have a substitute for operation in cases amenable to operation. Our experience thus far by no means warrants us in regarding it as more than an adjuvant to operation.

Personal Cases.—From February, 1902, to January, 1903, I have treated in private or had under my direction at the General Memorial Hospital seventy-five cases of malignant tumors. The treatment at the hospital has been conducted by Mr. W. P. Agnew and Dr. James Ogilvie. While it is entirely too early to speak of permanent results in these cases, the immediate results have been sufficiently striking to deserve careful consideration. Of these cases twenty-five were sarcoma of the various types; seventeen round-celled, three spindle-celled, one melanotic round-celled, and in five the variety was doubtful. Twenty-one were carcinomas of the breast (seventeen inoperable). In four the treatment was used as a prophylactic measure.

Of the three cases of spindle-celled sarcoma, one, a recurrent sarcoma of the superior maxilla, showed no improvement; one, a recurrent sarcoma of the chest wall, is still under treatment; one, a spindle-celled sarcoma of the cheek, is still under treatment, with slight improvement.

Still another case, formerly under my care, a spindle-celled sarcoma of the abdominal wall and pelvis, the size of an eight months' pregnant uterus, was treated for seven months by Dr. Skinner of New Haven, with general improvement but slight local diminution.

Of the seventeen cases of round-celled sarcoma, all inoperable, four have disappeared entirely, yet in every case a recurrence has taken place in less than a year. In all of these cases the *x*-ray applications were made four times a week, and continued over a period of many months. I think the histories of these cases are of sufficient interest to warrant a brief mention:

CASE I—*Very Extensive Recurrent Round-celled Sarcoma of the Neck, Both Sides, Superior and Infraclavicular, Pectoral and Axillary Regions on One Side and Mediastinal Glands.*—(The early history of this case is given in full in Transactions of the American Surgical Association, 1902.) The patient, M. A., aged forty-five years, was confined to bed and in such a hopeless condition that she was not expected to live more than two months. The toxins had been used and abandoned. On February 10, at the General Memorial Hospital, I began the *x*-ray treatment purely as an experiment. The improvement was more striking and rapid than in any other case that I have observed. The photographs show the changes that took place. No photograph was taken of the original condition, the disease having decreased one-third when the first photo was taken. The tumors steadily disappeared, and by July 1 there remained only a small nodule the size of an almond anterior to the sternomastoid muscle. This I removed under ether purely for pathological study, and the examination by Dr. Geo. Biggs of the New York Hospital confirms the original diagnosis and is of great interest. The patient had regained her normal strength and went to the country for the summer. She returned on September 24 with a local recurrence the size of an English walnut in front of the ear in the lower portion of the parotid. Both groins were filled with multiple tumors, varying in size from a hen's egg to a pigeon's egg. In addition there was an intraabdominal tumor, smooth, globular, fairly movable, apparently originating in the ascending colon or its mesentery. There was undoubted constriction of bowel at this point. Her condition again seemed hopeless, but I resumed the *x*-ray treatment, and in three weeks the nodule in the parotid region had entirely disappeared. At present the groin tumors have entirely disappeared, and the tumor in the abdomen has decreased about one-half. January 19, 1903: The abdominal

tumor is steadily decreasing and the patient's general health is good.

Case II—*Round-celled Sarcoma of Femur, Involving Two-thirds of Shaft.*—A. G., aged nineteen years. Swelling first noticed in lower portion of left femur in November, 1901. This gradually increased in size, being accompanied by loss of weight and deterioration of general health. February 5, 1902, physical examination showed a large tumor extending from the condyles of left femur to the junction of middle and upper third. There was a fusiform enlargement of the entire lower two-thirds of the femur. On the outer aspect of the thigh, about one and one-half inch above the joint, there was a soft fluctuating area just covered by thin and reddened skin. There was a slight impairment of the functions of the joint itself. An incision was made, under ether, into the fluctuating area and two to three ounces of clear serum, similar to that which is found in cystic degeneration of sarcomatous tissue, was evacuated. A curette was passed into the cavity of the bone and typically sarcomatous tissue removed. Microscopical examination by Dr. E. K. Dunham showed it to be a round-celled sarcoma. The patient absolutely refused operation. The *x*-ray treatment was tried entirely as an experiment, four exposures a week being given for a month, at the end of which time the circumference of the tumor had decreased one inch. The treatment was discontinued for two weeks, during which interval the tumor had again increased nearly a inch. The treatment was resumed, and at the end of another month the circumference of the thigh over the center of the tumor was one inch less than the original measurement The treatment was continued the entire summer up to December, 1902. In June he developed some râles in the chest which caused suspicion of lung metastases, but this condition cleared up, his general health improved, and he gained twenty pounds in weight.

December 1, measurement of the left leg was the same as that of the right. There was still some thickening in the lower part of the femur. The old sinus, which had never healed after the exploratory incision, was enlarged under ether and carefully curetted. Examination of the tissues failed to show any trace of sarcoma.

January 15, 1903: During the past six weeks the patient has lost considerable weight, about twelve pounds, and while the leg shows no increase in size, he has slight evening rise of temperature, suggesting possible metastases.

January 21, 1903: Careful physical examination shows a metastatic tumor about 3 inches in diameter in the left pectoral region, freely movable and apparently situated between the muscle and superficial fascia. There is also a small, deeply situated mass in the lower dorsal region just to the left of the spinous processes. These masses are undoubtedly metastatic tumors, and account for the recent loss of weight. The tumor in pectoral region was removed under ether anæsthesia February 4, 1903, and was typical round-celled sarcoma.

Case III—*Sarcoma of the Parotid*—Mrs. M. H., aged fifty-seven years. Small nodule in the region of the left parotid first noticed seventeen years ago. First operation in May, 1901. Recurrence in August. Second operation in January 1902. Impossible to remove entire growth, and the tumor grew very rapidly after that. In April the patient was admitted to the General Memorial Hospital, being given four exposures a week for six weeks, and while at first there was quite some improvement, the treatment soon lost its effect upon the growth. Later the mixed toxins were given in addition to the *x*-ray, but without causing further improvement.

Case IV—*Small Round-celled Sarcoma of the Pectoral Region.*—E. M., aged thirty-five years. Family history good. Had been twice operated upon for round-celled sarcoma of the right pectoral region by Dr. Maurice H. Richardson of Boston, microscopical examination made by Dr. W. F. Whitney at the Massachusetts General Hospital having proved the growth to be round-celled sarcoma. The last operation was performed in October, 1901. The disease then involved the pectoral and axillary regions so widely that it was impossible to make a complete removal. Amputation of the upper extremity was considered, but not thought advisable. The patient was referred to me by Dr. Richardson in October, 1901. The mixed toxins were administered five to six times a week for three months in doses sufficient to produce a marked reaction. The tumor softened, and in January, 1902, a spontaneous opening occurred with evacuation of about a pint of necrosed tumor tissue, as a result of which the growth diminished about two-thirds.

In February, 1902, the *x*-rays plus toxins were administered, causing continued decrease in the size of the tumor. In June, 1902, the growth had entirely disappeared, and the patient returned to Massachusetts in good condition. Since that time he has been working hard every day and has gained twenty pounds in weight. Recent examination, January 5, 1903, shows the patient's general condition still perfect, but about two inches below the clavical, in the pectoral region, there is a small movable nodule, the size of a hickory nut. The patient returned for treatment February 3, 1903, and the tumor has again nearly disappeared under toxins and *x*-ray treatment.

Case V—*Small Round-celled Sarcoma of the Back.*—W. J., aged eight years, family history good. In the latter part of August, 1901, the patient fell from the stoop, striking the back. Two or three weeks later the mother noticed a swelling over the left scapular region, which increased in size rather rapidly. It was soft and fluctuating from the start. The patient was referred to me in December, 1901, by Dr. Polhemus of Nyack, N. Y. A physical examination at that time showed a cystic swelling, the size of an orange, in the left scapular region. The skin was normal, the tumor fluctuating, situated apparently just beneath the skin and superficial fascia. With a small trocar several ounces of dark blood were withdrawn. The diagnosis of hæmatoma was made, and on January 12, an incision was made under ether anæsthesia. About half a pint of fluid blood with some clots was evacuated. There was no evidence of any tumor at this time. The wound was closed without drainage and healed by primary union. Two to three weeks later, the tumor slowly began to re-form; it was still cystic in character and increased steadily in size, until, on May 6, it had become about one-third larger than prior to the first operation. A second operation was performed. This time, in addition to fluid blood and clots, there was a slight thickening of the walls of the cyst, which made me suspect sarcoma. A portion of this thickened tissue was removed and examined by Dr. H. T. Brooks, Professor of Pathology at the Post-Graduate Hospital, who pronounced it small, round-celled sarcoma. Two weeks after the operation, before the wound had entirely healed, the *x*-ray treatment was begun and continued two to three times a week during the

entire summer, with the result that by October 1 the growth had entirely disappeared. In the middle of October he was taken with an attack of scarlet fever which confined him to the house for eight weeks, during which time he had no treatment. I did not see him again until early in December, when there was a well-marked local recurrence about the size of a hen's egg. The *x*-ray treatment was again advised but carried out very irregularly, as the boy lived out of town. In January regular treatment was begun, three times a week, by Dr. Raymond of New Rochelle, and pushed to the point of causing a slight dermatitis. Yet, in spite of this, the growth showed an increase rather than a decrease in size. January 20, 1903, I excised the tumor.

Case VI—*Sarcoma of the Frontal Sinus—Traumatic.*—Mrs. T., aged sixty years. The tumor appeared in the right frontal region near the median line, just above the orbit, eighteen years ago, immediately after a fall. It remained very small, until four months ago, when it began to increase rather rapidly in size. The patient was referred to me by Dr. Geo. Ben Johnston of Richmond, Va., and entered the General Memorial Hospital November 24, 1902. The combined *x*-ray and toxin treatment was begun, but the patient was so weak that she was unable to take more than one-quarter drop of the toxins. After two weeks' treatment the tumor had considerably softened and she was able to see better from the eye which was nearly closed at the time the treatment was begun. The patient's general condition, however, became weaker and the treatment had to be discontinued January 5. The treatment was resumed two weeks later and the patient is slowly improving.

Case VII—*Recurrent Sarcoma of the Testicle.*—R. M. B., thirty-four years old. Retroperitoneal tumor the size of a man's head, with metastatic tumors of the neck. The tumor of the testis was removed a year before. The mass in the abdomen was first noticed in the spring of 1902. The patient had had a long period of *x*-ray treatment prior to his admission to the hospital, August 27, 1902, without effect. He was treated at the General Memorial Hospital for one month with the *x*-ray in conjunction with the toxins, but the patient's general condition was so bad that the treatment could not be given with regularity or pushed to any extent. The treatmeat was abandoned and the patient returned home unimproved.

Case VIII—*Recurrent Round-celled Sarcoma of Testis.*—A. W. Disease was first noticed two years ago. Testis removed in July, 1902, by Dr. Gerster. Recurrence in upper part of scrotum and groin. Partial removal in October, 1902. *X*-ray, combined with the toxin treatment, begun November 25, 1902. Slight improvement; very foul discharge present at beginning, nearly ceased. General condition not so good. Recovery doubtful.

Case IX—*Sarcoma of Neck, Recurrent.*—J. V. D., aged thirty-seven years. Tumor first noticed in March, 1902; operated upon November 24, 1902. Impossible to remove entire growth. *X*-ray treatment begun December 24, 1902. Still under treatment; little effect upon the growth noticed thus far.

Case X—*Sarcoma of Right Pectoral Region and Neck.*—A. P., male, forty-five years old. The tumor was first noticed two years ago. No operation. At present there is a tumor in the right pectoral region, apparently involving two ribs, and a tumor the size of an egg in the right cervical region. *X*-ray treatment begun December 31, 1902. At present, February 25, 1903, there has been no appreciable change noticeable.

Case XI—*Very Large Inoperable Lymphosarcoma of the Neck.*—G. C., male, aged thirty-eight years. First signs of the disease noticed one and a half years ago. Two operations since. At the last one the growth was found so deeply attached that no attempt was made to remove more than a specimen for microscopical examination. The patient entered the General Memorial Hospital, September 19, having had about forty *x*-ray treatments prior to admission, with no effect upon the growth. *X*-ray plus toxin treatment advised, but continued for one week only, when the patient decided to have the treatment carried out at home. The case was regarded as hopeless.

Case XII—*Sarcoma of Neck.*—L. S. H., aged fifteen years. First operation November, 1901, by Dr. Dowd. Recurrence shortly afterward. Second operation September, 1902, by Dr. Dowd. The *x*-ray treatment was started September 29 as a prophylactic, and continued four times a week, for three months, when the patient was discharged. At present there is no return.

Case XIII—*Melanotic Sarcoma of the Iliac Glands.*—Mrs. N., aged thirty-seven years. Five years ago the primary tumor in the ankle was removed; no local recurrence, but four operations since performed for recurrent growths in the femoral and iliac regions. *X*-ray treatment was begun in February, 1902, and continued fairly regularly for nine months. The growth was held in check, but there was no marked decrease in size. At present, March 5, 1903, slowly improving; she has gained fifteen pounds in weight.

Case XIV—*Spindle-celled Sarcoma of the Cheek and Back.*—Mr. W., aged forty-one years. The tumor appeared in the skin of the left scapula in the early fall of 1902; at about the same time a similar growth appeared in the skin over the angle of the jaw on the left side and gradually extended by infiltration of the adjacent skin. Growth was rather rapid. The tumor of back was removed by Dr. Tomes of Brooklyn; examination showed it to be spindle-celled sarcoma. A section of the tumor of the face, examined by Dr. Geo. P. Biggs, showed it to be fibrosarcoma; it was considered to be of a low type of malignancy. The *x*-ray treatment was begun in October, 1902, four times a week. In addition to this the toxins were given, chiefly in the scapular region, occasionally in the growth of the face. The tumor diminished considerably in size under two and a half months' treatment. The toxins were then discontinued, but under the *x*-ray treatment alone the growth began to increase rapidly and the combined treatment was resumed December 20. At the present time, January 12, 1903, the tumor of the face is slowly decreasing again, in size, and there is no sign of a return in the back. February 25, 1903, the patient is losing flesh rapidly and shows signs of internal metastases.

Case XV—*Spindle-celled Sarcoma of the Superior Maxilla.*—Mr. T. N., aged forty-six years. First signs of the disease were noticed in January, 1899. In June a mass the size of a walnut was removed through the mouth from inner side of antrum. The swelling returned within a few weeks, and partial removal of the superior maxilla was done in August. The swelling again returned, and in June, 1900, he entered the Presbyterian Hospital of this city, where Dr. McCosh performed another very extensive operation. In October the patient returned to the hospital with a large recurrent sarcoma, which was considered inoperable by Dr. McCosh. The toxins were then tried for several months, and while, at first, the improvement was striking, they soon lost their influence upon the

growth and were discontinued. February 10, 1902, the *x*-ray treatment was begun and given for three weeks, without effect upon either pain or growth of tumor.

Case XVI—*Sarcoma of the Right Thigh, Originating in the Femoral Glands.*—W. H. D., aged sixty-five years. Enormous swelling of thigh and leg. *X*-ray treatment by another physician from the end of June to October 21, with the result that the tumor greatly decreased in size and the œdema disappeared. Skin of thigh and abdomen deeply bronzed. In November, 1902, the disease again began to increase in size. *X*-ray treatment was resumed December 15, being given three times a week of five to six minutes' duration. The effect upon the tumor masses was very remarkable; they immediately began to soften and disappear, and at the end of two weeks the thigh had decreased to almost the size of the other. With the disappearance of the tumor general health rapidly deteriorated. The treatment was stopped. The patient continued to fail and died on the 5th of January.

Case XVII—*Recurrent Spindle-celled Sarcoma of the Chest Wall.*—Mr. S., *x*-ray treatment as a prophylactic measure, December, 1902. Six treatments only were given.

Case XVIII—*Small Round-celled Sarcoma of the Thigh.*—Mr. W. J. P., aged twenty-two years. Recurrence after three operations within six months. Toxin and *x*-ray treatment both tried persistently during the summer of 1902 for three to four months. Apparent retardation of growth at first, but later growth continued uncontrolled by treatment and finally metastases developed in lung.

Case XIX—*Round-celled Sarcoma of Thigh.*—Mrs. M. V., aged thirty-seven years. Recurrence after two operations within six months. Combined *x*-ray and toxin treatment given for a month without the slightest apparent effect.

Case XX—*Round-celled Sarcoma of Parotid.*—Mr. R. B., aged twenty-five years. First noticed tumor in September, 1901. Operation in November. Recurrence in December, and in January a second operation was performed, but it was impossible to remove the entire growth. Neither the toxins nor the *x*-ray, which were tried successively, showed any influence upon the disease. The patient's general condition rapidly failed and he died early in April.

Case XXI—*Sarcoma of Neck.*—Mr. K., aged fifty years. Sarcoma the size of an egg; inoperable. *X*-ray treatment begun September 19. Duration of treatment too short to note result.

Case XXII—*Sarcoma of Parotid.*—Mrs. B., aged thirty years. Tumor the size of an orange, firmly fixed to the deeper parts and entirely inoperable. *X*-ray treatment began April 7, 1902, at the General Memorial Hospital, and continued for four weeks. As there was no apparent improvement at the end of this time, the treatment was discontinued.

Case XXIII—*Recurrent Sarcoma of Orbit.*—E. B. T. Combined toxin and *x*-ray treatment was given at the General Memorial Hospital from June to October. The growth was at first held in check, but later the treatment had apparently no effect.

Case XXIV—*Intraabdominal Sarcoma, Retroperitoneal*—I. A., aged forty-two years. *X*-ray. Two years' duration. Symptoms of involvement of right kidney. *X*-ray begun November 10, 1900, continued for six weeks. Slight improvement in general health at first, later no effect.

Case XXV—*Sarcoma Right Superior Maxilla.*—J. S. aged fifty-five years. First noticed ten years ago. Operated upon 1894, 1900, 1901, 1902. *X*-ray begun January 5, 1903. Very little effect noticed in three weeks' treatment.

Case XXVI—J. B., male. Family history negative. In the fall of 1901 the patient noticed a small, hard painless nodule in the outer part of the left axilla. This increased steadily in size until April 9, 1902, when it was operated upon at the Seney Hospital, Brooklyn, in the service of Dr. L. S. Pilcher. The history kindly given me by the house surgeon, stated that there was a tumor mass along the anterior border of the left axilla under the greater pectoral muscle, which was removed by dividing the muscle. The axilla was found filled with hard and enlarged glands, varying in size from that of a bean to a pigeon's egg; some of these glands were closely adherent to the great vessels of the neck. These glands were carefully dissected out. (The specimen was lost and no microscopical examination was made, but supposed to be sarcoma.)

Soon after leaving the hospital, a local return was noticed, and in the latter part of June, 1902, the patient was referred to me for treatment. Examination at that time showed the left pectoral region occupied by a tumor involving the pectoral muscle, and extending from the clavical around into the axilla. It was fairly firmly fixed and inoperable. The patient was admitted to my service at the General Memorial Hospital, and the *x*-ray treatment was administered four times a week by Mr. Agnew and continued the entire summer until the middle of August, when the patient had a slight attack of pneumonia. At that time the tumor had entirely disappeared. After recovering from the pneumonia, he returned to his home in Brooklyn, but came back for outdoor treatment three times a week for nearly two months, the idea being to prevent a return of the disease. At present the boy is in perfect health, without any trace of disease to be found. January 19, 1903: The patient has recently developed enlarged glands above the clavicle while regularly taking the *x*-ray treatment. One of these glands I removed on January 10, and microscopical examination by Dr. E. K. Dunham showed it to be tuberculosis of a lymphatic gland.

Summary of the Cases of Sarcoma.—Twenty-five cases of inoperable sarcoma were treated between February, 1902, and January, 1903. Anatomically classified, they are as follows: Six of the neck; three of the thigh; three intraabdominal cases; three of the parotid; two of the pectoral region; two of the testis; one each of the femur, back, frontal sinus, iliac fossa, chest wall, and superior maxilla.

In four cases of inoperable round-celled sarcoma the tumors entirely disappeared, and up to November 17, the time of the reading of the paper, three had remained free from recurrence.

At present, January 23, 1903, recurrence had taken place in every case. In one of these cases, an inoperable sarcoma of the neck and pectoral region, which disappeared in June, there was extensive metastatic development in both groins and the abdomen in September. The groin tumors have entirely disappeared under renewed *x*-ray treatment, and the abdominal tumor is slowly decreasing in size. As to the present condition of the other four patients, I would refer to the histories of the respective cases given in the foregoing.

Seven other cases have shown improvement. Three of these were round-celled, one melanotic and two spindle-celled. One of the latter is so recent that it is hardly fair to consider it. In another spindle-celled or fibro-sarcoma the toxins were used in addition to the *x*-ray.

In thirteen cases no improvement whatever was noted; one of these was a round-celled sarcoma of the upper portion of the orbit; one an intraabdominal sarcoma, retroperitoneal; one a lymphosarcoma of the neck; one a retroperitoneal round-celled sarcoma secondary to sarcoma of the testis; one a round-celled sarcoma of the muscles of the thigh; one a round-celled sarcoma of the parotid; one a sarcoma of the iliac fossa; one a spindle-celled sarcoma of the superior maxilla.

In two cases the treatment has only been used about a week, and it is too early to state the result. In one case, a sarcoma of the neck, in which the treatment was used as a prophylactic, there has been no recurrence.

In five other cases of sarcoma in which I advised the *x*-ray treatment, but in which it was carried out by other men, I have been watching results with interest. One of these, a recurrent, round-celled sarcoma of the superior maxilla, involving the orbit, was treated by Dr. W. B. Snow for nine months with very remarkable improvement during the first four to five months. The growth at one time had nearly disappeared, but gradually extended more deeply into the orbit and frontal sinuses, causing death in November. The second case, a sarcoma of the mastoid region, very nearly disappeared, under treatment by Dr. W. J. Morton begun in January, 1902, but later the patient developed two or three attacks of cellulitis of the neck with much discharge from the ear, greatly weakening her general condition. She finally died in November, 1902. In a third case, a very extensive round-celled sarcoma of the skull, the *x*-ray and toxins were both used with very little if any effect in checking the disease, which proved fatal in two months. In the fourth case, a sarcoma of the neck and tonsil, of very rapid growth, in a girl of ten, both *x*-ray and toxin treatment were advised and carried out in Baltimore under the direction of Dr. Finney. There was slight improvement at first, but later the tumor grew rapidly in spite of treatment. A fifth case, a spindle-celled sarcoma of the abdominal wall and pelvis, the size of an eight months' pregnant uterus, has shown remarkable improvement under the *x*-ray treatment, administered by Dr. C. E. Skinner of New Haven. The patient was under my care for a year, and while at first the tumor decreased greatly under the mixed toxins, later the treatment failed to check growth and *x*-ray was advised. She has been under treatment now for one year and her general health is much improved. The tumor has decreased some in size, but is still large.

I have, further, treated one case of advanced Hodgkin's disease with the *x*-ray, with remarkable improvement.

The patient, W. B., aged forty-three years, was referred to me September 25, 1902, by Dr. Frank Hollister. No tubercular history. In the spring of 1902 he first noticed a small swollen gland in the left sub-maxillary region. This was quickly followed by a similar swelling on the right side of the neck. In a short time the entire sub-maxillary and submental regions were filled with large glandular masses. Then the glands in the axilla and groins began to enlarge. At the time of his admission to the hospital he had lost considerable weight. In addition to the large glandular tumors already mentioned, there was a hard, immovable tumor consisting of the greatly enlarged spleen, occupying the entire left side of the abdomen, extending to within two inches of the right ant. sup. sp. and within one inch of the symphysis pubis. The patient was put upon the *x*-ray and toxin treatment, the *x*-rays being applied to both his neck and abdomen, thirty minutes a day, four times a week. Frequent blood counts showed the trouble to be typical Hodgkin's disease. Improvement was very quickly noticeable and has continued constant until the present time. He was discharged from the hospital November 1, 1902, and since that time the *x*-ray treatment has been continued three times a week. At present, February 25, 1903, the patient is apparently well; he has regained his normal weight and resumed his usual work. The cervical glands are still very slightly enlarged and the splenic tumor is about one-third the original size at the beginning of treatment. It should be noted that Williams's two cases of Hodgkin's disease, which showed remarkable improvement under *x*-ray treatment, both relapsed in about six months.

Cancer of the Breast.—Twenty-one cases.—In fourteen of these the disease was recurrent and inoperable. One case was advanced primary carcinoma, but not beyond operation. The patient, however, absolutely refused surgical intervention. The *x*-ray treatment was given very irregularly, but the disease has been held in check since March, with slight improvement. In four cases the *x*-rays have been used immediately after operation as a prophylactic measure. On one of these, a carcinoma of rather rapid growth, in a young woman, aged thirty-three years, I operated in May, removing the breast, portion of the pectoral muscle, and axillary glands. I advised the *x*-ray treatment, and about a month after operation the patient went to a private institution, in New York, where she received thirty-five treatments. The patient states that a static machine was used and exposures were made without removing the clothing, and that no effect whatever was noticed upon the skin. During the treatment she had severe neuralgic pain in the scapular region and arm. Physical examination November 20, 1902, showed two hard, recurrent masses, one just beneath the clavicle, attached to the periosteum of the ribs, another on the inner border of the sternum, very firmly fixed. The right arm is much swollen, being one inch larger than the left. The patient has a great deal of pain.

In this case the disease developed and continued to progress in spite of the *x*-ray treatment. However, I believe that the treatment was not pushed to the limit necessary to insure the best result. In November she was treated with a coil and with the exposures pushed to the limit of a dermatitis. She has shown some improvement.

The second case, an advanced, recurrent cancer of the breast, in a single woman, aged forty-eight years. Primary operation, consisting in removal of the tumor itself, without axillary glands or breast tissue, was done in India. The recurrent growth involved both the greater and lesser pectoral muscles and extended into the axilla. On June 30, at the General Memorial Hospital, I removed the diseased tissues with the pectoral muscles as far as possible, but was unable to do a radical operation. Considerable carcinomatous tissue was undoubtedly left behind. She was immediately put upon the *x*-ray treatment and has since July 1, had thirty exposures, with the effect that the induration in the neighborhood of the wound has entirely disappeared, and there is at present no trace of any thickening or hardening either in the pectoral or axillary regions and there is no swelling of the arm. (January, 19, 1903, there is no evidence of the growth present.)

In the third case, operation for carcinoma of the breast with removal of the axillary glands was performed in May, 1902, in a young woman, aged thirty-two years. The *x*-rays have been applied twenty-

five times since as a prophylactic. This patient has no trace of a return.

In the fourth case, a carcinoma of both breasts in a woman aged thirty-three years of very rapid growth and extensive involvement of the axillary glands on both sides, double operation was performed September 9, 1902. The breast tumors were about the size of two fists each, and large masses of glands filled up the axillæ. Sufficient apparently healthy skin was found to close the wound without skin-grafting and the *x*-ray treatment was begun immediately after the wounds had healed. The patient has now had seven weeks' treatment and is at present in good health.

In three cases of recurrent carcinoma of the breast, the recurrence being in the form of small nodules just beneath the skin in the vicinity of the scar, the tumors disappeared entirely after three to four weeks' treatment. In two cases, however, a return followed a few weeks later. In one case the recurrent growth is again yielding to the treatment. The other case is being treated in a distant city. The third case is very recent.

Still a fourth case (recurrent carcinoma of breast) of this kind was in a patient of mine who was referred to Dr. Morton last January for *x*-ray treatment. After three to four weeks, the tumor (the size of a bean) disappeared, but the patient soon developed signs of lung involvement and died a few weeks later.

Most of the other cases were large recurrent masses in breast and axilla, and while nearly all of them showed some slight improvement, in none has the growth entirely disappeared.

Breast Cases.—Case I.—*Cancer of the Left Breast*—Miss D., aged sixty-four years. The patient had been operated upon three times, the last time by myself, in June, 1901, when a small recurrent nodule, the size of a Lima bean, was removed from the periosteum of the seventh rib, at about the internal mamillary line. Six months later another small nodule appeared and was excised under ether In the early part of March a small nodule could again be felt, apparently starting in the periosteum of the fifth rib. This disappeared under six weeks' treatment with the *x*-ray. The patient then left the city, and the subsequent history shows that the nodules returned shortly after treatment was discontinued. Final result unknown.

Case II.—*Cancer of Left Breast.*—Miss G., aged iorty-eight years. Was operated upon in Calcutta, January, 1900, the tumor only being excised; breast not amputated and axilla not opened. Noticed recurrence about a year later. Operation at the General Memorial Hospital, June 27, 1902. A large mass deeply involving the pectoral muscle and axillary glands was removed. Thorough removal could not be accomplished on account of the too extensive involvement. As soon as the wound had healed the patient was put upon the *x*-ray treatment, which was continued three times a week for about two months, then, after an interval of a month's rest, was resumed in October. The indurated area in the pectoral region, which was left after operation, has resumed a normal condition and there has been no swelling of the arm. Up to the present time, February 25, 1903, the patient has had forty treatments and is in excellent physical condition, without any local signs of disease or metastases.

Case III—*Cancer of Left Breast.*—Mrs. M., aged fifty-one years. Left breast removed for cancer eight years ago, a second operation done one year later. In July, 1902, she developed a mass of enlarged glands in the left supra-clavicular and cervical regions. *X*-ray treatment was begun at the General memorial Hospital on July 29, and continued until October 22. The glands showed decrease in size, but did not disappear.

Case IV—*Cancer of Right Breast.*—Mrs. B., aged thirty-eight years. First operation was done in the early part of 1901, six weeks after it had been first noticed. The tumor recurred within six weeks, and on June 10, 1901, a second operation was performed at Bellevue Hospital, the breast and axillary glands being carefully removed. A little over a month after this the patient noticed a local return, consisting of two small nodules; the larger, the size of a Lima bean, just beneath the skin at the former site of the breast, the other somewhat smaller. After a month's treatment with the *x*-ray, three times a week, the nodules entirely disappeared.

Case V—*Cancer of Right Breast.*—Miss S., aged thirty-three years. *X*-ray used as a prophylactic measure. Removal of right breast and axillary glands for carcinoma in May, 1902. Primary wound healing; *x*-ray treatment immediately after for six weeks. Second period of treatment, October, 1902, for four weeks, three times a week. At present, January 12, 1903, there is no return of the disease.

Case VI—*Cancer of Right Breast.*—Mrs. H. A. H., aged forty-two years. No operation. Two tumors of right breast, one the size of a goose egg, the other that of a walnut; axillary glands involved; tumor not attached to the pectoral muscles and not considered inoperable. Operative treatment very strongly advised, but absolutely refused by patient. *X*-ray treatment begun in March, 1902. Patient came for treatment very irregularly and for weeks had no treatment at all, seldom more than two treatments a week. In spite of this the tumors diminished considerably in size, and at present, January 12, 1903, are not more than one-third of their original size. The disease is typical carcinoma of the breast, although no microscopical examinations have been made in this case.

Case VII—*Recurrent Cancer of Left Breast.*—Mrs. H., aged fifty years. Three operations have been performed within the preceding two years, under cocaine. The patient absolutely refused to have the breast removed. A small local return, apparently in the periosteum of the rib, just above the breast, appeared in December, 1901. In January, 1902, I referred the patient to Dr. Morton for *x*-ray treatment. A small nodule, the size of a bean, entirely disappeared under four weeks' treatment with the *x*-ray. In spite of this fact, a few weeks later, the patient developed symptoms of involvement of the pleura lung and died six weeks later.

Case VIII—*Cancer of Breast, Recurrent.*—Mrs. M., aged forty-four years. Tumor of right breast first noticed two years ago. Breast removed February 1, 1902; recurred a few months later. *X*-ray treatment begun December 22, 1902. Condition at time: Extensive local recurrence involving pectoral region and axilla with much œdema of arm. Severe pain. After three weeks' treatment at the General Memorial Hospital no decrease in pain and swelling of arm increased. Local condition not improved.

Case IX—*Cancer of Breast, Inoperable.*—Mrs. S., aged sixty-two years. Tumor appeared December, 1899. Inoperable July 15, 1902, when *x*-ray treatment was begun September 19 and continued twice a week until November 3. Axillary glands decreased in size; no change in size of breast tumor. Patient then went to a nearer hospital for treatment.

Case X—*Cancer of Breast*—Mrs. McC., aged forty-seven years. Tumor in left breast of two and one-half years' duration. Operation two years ago. *X*-ray treatment begun November 26, 1902. Result: no improvement.

Case XI—*Cancer of Breast.*—Mrs. M., aged fifty

years. Tumor of left breast. Recurrent after operation. *X*-ray treatment begun September 5, 1902, at the General Memorial Hospital; continued three times a week. Decrease in pain and softening of tumor. Improvement temporary.

Case XII—*Cancer of Breast.*—Mrs. G., aged forty-two years. Tumor of right breast, first noticed in April, 1902. No operation. When she consulted me, May 2, 1902, the tumor was inoperable and axillary glands much involved. *X*-ray treatment from May 15 to December, 1902; twice a week from May to September, later three times a week. August 15, pain had disappeared. September 8, enlarged glands had nearly disappeared. Slight improvement in main tumor.

Case XIII—*Cancer of Breast.*—Mrs. B., aged sixty years. Right breast removed for carcinoma January, 1898. Recurred March, 1902. Large tumor over sternum and involving same; axillary glands also involved. *X*-ray treatment begun November 11, 1902, and given four times a week at the General Memorial Hospital. Result: slight temporary improvement

Case XIV—*Cancer of Breast.*—Mrs. F.; *x*-ray treatment begun August 18, 1902, twice a week. No improvement. Duration of treatment four weeks.

Case XV—*Cancer of Breast.*—Mrs. C., aged fifty-four years. Tumor first noticed December, 1900. Operation July, 1902. Recurrence. *X*-ray treatment begun September 8, 1902. Duration of treatment, six weeks. Result: Improved.

Case XVI—*Cancer of Breast.*—Mrs. M., aged fifty-four years. Tumor of right breast. First operation in 1883; second in 1898; third in 1901. Local recurrence with axillary involvement. *X*-ray treatment begun September, 1902, three times a week. Slight improvement.

Case XVII—*Cancer of Both Breasts with Axillary Involvement; X-ray Treatment Immediately after Operation as Prophylactic.*—L. D., single, aged thirty-three years. About two years before noticed tumor of breast soon after severe injury from a fall. No operation until September, 1902, when both breasts were entirely transformed into large tumors and both axillæ were filled with glands the size of hens' eggs; no œdema of arms. She was referred to me by Dr. Tracy of Meriden, Conn. I removed both breasts and axillary glands at same operation, and the wounds healed by primary union. The *x*-ray was begun at once and continued four times a week until December 23. While taking the *x*-ray treatment several small shot-like carcinomatous nodules developed in the skin near the site of cicatrix of left side. The patient's health remained perfect until December 30 when she began to lose flesh and develop symptoms pointing to metastases.

Case XVIII—*Cancer of Both Breasts, Inoperable.*—R. P., aged forty-one years. First noticed tumor in September, 1902. Probable duration much longer. Extensive involvement of both breasts and axillary glands. Skin nodules over entire chest, abdomen, back and neck, with secondary tumor in orbit. *X*-ray treatment begun December 29, 1902.

Case XIX—*Cancer of Breast.*—Mrs. McD., aged forty years. Cancer of right breast of four years' duration. Inoperable, involving periosteum of ribs and sternum. *X*-ray treatment begun December 8, 1902. Very marked improvement; decrease in size; cessation of pain.

Case XX—*Cancer of Breast.*—Mrs. R., aged forty-nine years. Tumor of right breast of fifteen months' duration. Operation two months after the growth was first noticed. Speedy return, Inoperable, with extensive œdema of arm, and great pain. *X*-ray treatment begun December 5, 1902. The pain was increased by the *x*-ray; swelling of arm not changed. Died one month later.

Case XXI—*Inoperable Carcinoma of Both Breasts with Metastatic Tumor of Orbit and Extensive General Carcinomatosis of Skin.*—Mrs. P., aged forty-four years. First noticed tumor of orbit few months ago. Did not know she had trouble with breasts, although both were completely involved with typical carcinoma. Small nodule removed from skin confirmed diagnosis. *X*-ray treatment begun December 28, 1903; February 25, 1903, skin tumors much improved. Pain less and general condition better, though the patient is losing flesh.

Cheloid of Both Arms.—E. F., male, aged sixty years. Cheloid following burns of arm eighteen months ago. *X*-ray treatment begun September 26, 1902, four times a week. No improvement.

There were fifteen cases of epithelioma of the head and face, including three of recurrent cancer of the tongue, and three of the superior maxilla. In none of these has the growth entirely disappeared. In one case, a large rodent ulcer of the forehead, there is only the slightest trace remaining. In a second case, a very extensive primary epithelioma of the mastoid region, in a man aged sixty-five years, the growth increased in size considerably. The treatment was kept up for more than six months. During the last six weeks the improvement ceased, and the patient was finally discharged in December, 1902. In one, case of epithelioma of the chest, one-half an inch in diameter, the growth entirely disappeared in four months

Abdominal Cancer.—Up to January 1, 1903, I have observed eleven cases of abdominal cancer treated with the *x*-ray: Two cases of carcinoma of the sigmoid and rectum, five of the uterus, one of the bladder, three large intraabdominal sarcomas, one of them a very extensive growth, secondary to round-celled sarcoma of the testis, filling up the entire abdominal cavity. One case of inoperable recurrent cancer of the uterus involving the abdominal cicatrix, in a woman thirty-five years of age, showed no improvement after a month's treatment.

In a second uterine case, treated in August, 1902, involving the cervix, and considered inoperable by Dr. G. W. Jarman, the discharge ceased entirely after a few treatments, and at the end of three months Dr. Jarman stated that the disease had apparently entirely disappeared. I have not made a physical examination since the treatment was discontinued, but in a letter dated January 15, 1903, the patient states that she is in perfect health and has no vaginal discharge. No recent examination has been made, however, by her physician. The other uterine cases all showed decrease in discharge and the pain was diminished.

In one case, a carcinoma of the rectum and sigmoid, treated by my associate, Dr. Finley R. Cook, there has been decided decrease in the size of the sigmoid tumor, improvement in general symptoms, and several pounds gain in weight. The patient was getting worse rapidly before the treatment was begun. There has been, however, very little, if any, effect in controlling the pain, even larger doses of morphine being required than prior to the beginning of the treatment. In this case the interstitial injections of the mixed toxins were given in addition to the treatment with the *x*-ray, for a period of three months. (March 9, 1903: The patient is still under treatment, and the tumor has decreased so much that it can hardly be felt on palpation.)

My case of extensive inoperable round-celled sarcoma of the neck, pectoral region, and axilla, which disappeared under the *x*-ray treatment in June and recurred in September, is of further interest in con-

nection with the influence of the *x*-ray upon abdominal growths. When she returned in September, the most extensive recurrence, or rather, metastasis, was in the region of the ascending colon, forming a tumor the size of a large grape fruit, freely movable and apparently located in the mesentery of the ascending colon. Under the *x*-ray treatment with a high tube, four exposures a week, for the last six weeks, this mass has decreased one-half in size, although she is rather stout and has a thick layer of adipose tissue over the abdominal wall. (February 21, 1903. The tumor is still slowly decreasing.)

The Relative Merits of the Toxins and X-Rays in Inoperable Sarcoma.—The time has been too short and experience too limited up to the present to definitely decide this question. It is fair to say, however, that in several cases of inoperable round-celled sarcoma in which the toxins had been tried and failed, the *x*-ray caused entire disappearance of the tumors. Yet, all of these cases are of recent date, yet in all there has been a speedy recurrence.

On the other hand, in a much larger number of cases of inoperable sarcoma, the tumors have entirely disappeared under the toxins and remained well from three to ten years after treatment. I have had twenty patients with inoperable sarcoma remain well from two to ten years after the disappearance of the tumor under the mixed toxin treatment. Of these, fifteen patients were well from five to ten years.

I had the opportunity of observing the effect of the *x*-ray upon only three cases of spindle-celled sarcoma, and found it to be exceedingly slight in all. Yet, it is just in this class of cases—the spindle-celled—that the result of the toxin treatment has been by far the most satisfactory, nearly 50 per cent. of the cases of inoperable, spindle-celled sarcoma having disappeared under the treatment in my own experience. In the round-celled variety, however, upon which the influence of the toxins is much less pronounced, the immediate results from the *x*-ray treatment seem to have been the best. In one of my cases, a very large inoperable round-celled sarcoma, two-thirds of the growth had disappeared under the toxin treatment, and at this point the *x*-ray was used in addition to the toxins with the result that the entire tumor disappeared three months later.

In deep-seated and inaccessible growths the results from the toxins will probably prove better than from the *x*-rays.

There is no objection to using both methods of treatment at the same time, and there is reason to believe that the combined treatment will give better results than either used alone. There are a large number of cases of inoperable sarcoma treated either with the *x*-ray or the toxins, in which inhibitory action is almost, but not quite, sufficient to check the growth, and it seems but reasonable to suppose that the combined action of the *x*-rays and toxins might be sufficient not only to check the growth, but to cause it to disappear.

Technique.—I believe that it is impossible to lay down any dogmatic rules as to an ideal technique. The method is still in the early experimental stage; the question of the relative value of the static machine and the coil is still unsettled. The evidence at present would go to show, however, that the results are about as good from the use of one apparatus as another, provided the ray is sufficiently powerful. In tumors of large size, a 12-inch coil is probably better than an 8-inch, and a high tube better than a low tube. My own cases were treated with the Willyoung and Queen 12-inch coils. The method is wholly experimental as yet, and we are merely groping in the dark and here and there picking up facts that promise, when correlated, of being of great value in perfecting our methods. There is already one serious result that has come from the laity having, through the press, obtained exaggerated ideas of the value of this method.

Patients with cancer, always with the natural dread of the knife, and prone to try all means first, are seeking *x*-ray treatment when the tumors are in the early stages and easily removable. While some few of these cases may possibly be cured by the *x*-rays, probably a larger number will become inoperable before consulting the surgeon.

Dangers.—Numerous lawsuits have been brought for injuries from burns caused by either careless application of the rays, or unusual susceptibility on the part of the patients to their influence. It is, therefore, very important that, before undertaking to treat a case, the physician should guard himself against trouble of this sort. The patient should be told beforehand, that a burn may occur; that, in fact, it may be wise to push the treatment so far that in all probabilities a burn will occur. Patients must assume the risk of such results. In my own experience I have had only two slight burns, which healed up in a few weeks without a scar. One curious result, unlike anything I have thus far seen reported, occurred in the case of sarcoma of the femur that I mentioned above. This was a general, eczematous, bullous dermatitis, of very severe type, with a large amount of scab and exudate, starting in the area subjected to the rays and spreading over the entire body. This has yielded very slowly to treatment.

Danger of Toxæmia.—From too vigorous an application of the rays in large and very vascular tumors, the rapid breaking-down or tissue necrosis is followed by the absorption of so much of the toxins or products of degeneration, that the patient is liable quickly to develop the symptoms of toxæmia, which may easily prove fatal, as has been the case in several instances that have come to my knowledge. There is also the possible danger that in the rapid breaking down some of the living tumor cells may be carried to remote parts of the body, causing metastases.

With our present knowledge I do not believe we are justified in using the method in any but inoperable growths, and chiefly those of external origin. At present there is no convincing evidence that the *x*-rays do much good in internal growths, for example, cancer of the stomach, abdominal organs, including bladder, uterus, and rectum. I have tried the *x*-ray in a number of cases of this character at the General Memorial Hospital without much improvement. I should not advise the *x*-rays in any operable growths. It is far better to remove the tumor and then give *x*-ray exposures for a period afterward, as a prophylactic against recurrence. The value of this after-treatment can only be determined by systematic trial in a large series of cases over a long period of time. Yet there is a strong *a priori* reason for expecting beneficial results from such a source.

There comes up for consideration, however, a class of cases which, while operable, may, I think, be regarded as suitable for at least temporary treatment with the *x*-ray before resorting to operation. I refer to sarcoma of the extremities, in which the only operation would necessitate the sacrifice of the limb.

It might be argued with good ground that a delay of even a few weeks while trying the *x*-ray in such cases, for example, in a periosteal sarcoma of the femur or tibia, might be enough to allow metastases to occur in the lungs or elsewhere. On the other hand, it might be said with equal propriety, that the chance of curing, for example, a sarcoma of the femur,

even by hip-joint amputation, is so slight (hardly 2 per cent.) that the risk of delay might well be taken.

In still another class of really operable cases there are many who believe that the *x*-ray will yield better results than excision; that is, small epitheliomas of the face. In the discussion of inoperable cancer before the recent meeting of the British Medical Association, no less an authority than Malcolm Morris, who is himself a firm believer in excision as the only rational method of treatment in almost all forms of malignant disease, advocates the *x*-ray in many cases of operable epithelioma and rodent ulcer of the face, because of the excellent cosmetic results and destructive effect of the rays upon insidious non-evident foci. And yet, we must not suppose that all cases of small and superficial epitheliomatas of the face will yield rapidly to the *x*-ray. I have a woman under treatment with a small epithelioma of the bridge of the nose extending to the inner canthus of the eye, that has had *x*-ray treatment for five months with only very slight improvement. In another case, an epithelioma of the forehead, the treatment was continued steadily for nearly a year, before the disease disappeared. Thus far there has been a tendency to early recurrence in these cases.

My experience thus far leads me to believe that while in the *x*-ray we have a most valuable therapeutic agent for inoperable cancer of all varieties, in the great majority of cases the beneficial influence of this agent is only temporary. Yet, in a small proportion of cases, mostly superficial epithelioma and sarcoma, the tumors have disappeared and there is reason to hope that in a few of these cases a permanent cure may result.

These results while sufficient to warrant us in advising the treatment in all forms of *inoperable* malignant disease (not too far advanced) by no means justify us in offering this method as a substitute for operative treatment in primary operable tumors.

Conclusion.—Let us look for a moment at the results thus far obtained. We find abundant evidence that the *x*-rays have an inhibitory action on all forms of malignant tumors. Yet, the number of cases is insufficient to enable us to state what particular varieties are most susceptible to this influence. So far it would seem that sarcomas primary in the lymph glands yield most readily to the treatment. Superficial epitheliomas might be placed in the same category. Several cases of recurrent carcinoma of the breast have been observed in which the growths have entirely disappeared after prolonged exposures of the *x*-rays. Yet all these cases have been too recent to be classed as cured. In fact, *sufficient time has not yet elapsed in a single case of cancer treated with the x-ray to justify us in regarding it as cured.* While this should, on the one hand, prevent us from reporting patients as cured in whom the tumors have merely disappeared under treatment, it should not, on the other hand, lead us to minimize the importance of these immediate results, even be they no more than a prolongation of life or an alleviation of suffering. One cannot witness the marvellous melting away or disappearance of an undoubtedly malignant tumor under a few weeks' or months' treatment with the *x*-ray, without feeling that we have a new and powerful addition to our hitherto scanty means of attacking this disease. The knowledge of this new agent is so slight that there is added hope in our very ignorance. For by deeper insight into its nature, gained by further experience, we may hope to better utilize its power, and thus accomplish greater results. In the meantime, while the *x*-ray has a legitimate place in the treatment of *inoperable* cancer, present data do not warrant us in advising the method in *primary operable cases.*

5 Park Avenue.

SIGMOIDOPROCTECTOMY FOR CANCER OF THE RECTUM.

By GEORGE W. ROBERTS, M.D.,
NEW YORK.

In spite of the numerous methods which have been and still are advocated as beneficial to, or curative of cancer in general, the one resource which has stood the test of time and is of avail in any considerable proportion of cases, is the early and complete removal of all cancerous tissue by surgical means. We are now in possession of a tolerably good idea of the routes by which the growth extends, and have learned much of the reasons for our earlier failure in the surgical treatment of this affection.

We are obliged to assume that early recurrence after operation means that our operation has been incomplete, either necessarily or inadvertently. As this statement may be considered somewhat broad, it perhaps deserves elucidation. It refers to *early* recurrence only, for the question may arise in some of the later recurrences whether or not they are true recurrences at all. As we are not yet in possession of a well-accepted theory of the cause of cancer, it is quite possible that we shall ultimately classify the cancer which recurs from four to ten years after removal of the primary growth as an entirely separate lesion, dependent upon the continued action of the original cause, whatever that may be demonstrated to be.

We are familiar with the clinical behavior of the different forms of cancer, and we recognize that it now and then develops following operation, or recurs if you choose to use that term, at a date so late that it could not possibly have been present at the time of operation, and now have reached appreciable size long before the recurrence took place.

Pathological research has taught us that the macroscopic appearance of tissues contiguous to a cancerous growth is not to be trusted, that peninsulas and islands of cancer are of frequent occurrence; but above all, that the lymphatics many inches away from the primary growth not only *may* be, but almost always *are*, involved, even though the primary growth is still young. Furthermore, the microscope shows that although these lymph nodes are perfectly normal in macroscopic appearance, they may be cancerous, and that we have no test short of microscopic examination by which we can distinguish the healthy from the recently involved lymph nodes.

Working upon this basis, operators in various special fields have evolved, more and more, radical methods, all tending toward wide removal of the growth or the organ itself, and especially toward removal of the lymphatics in the centripetal direction as far as the anatomy of the part will permit. In other words, the tendency is toward removal of the lymphatics to such a distance that the procedure must be suspended on account of interference with vital organs.

The more marked examples of this tendency are to be found in the work of Halstead in his breast amputation, and in that of Kelley and Cullen in their work upon cases of uterine cancer. Not only does this work appeal to our surgical sense, but statistics are rapidly becoming available which justify the more thorough and far-reaching method. Especially does this apply to cases of

cancer of the breast, for, before the advent of the Halstead operation, many active surgeons questioned whether amputation and removal of the macroscopically diseased glands were worth while, whether such cases were not as well off if not operated upon.

To-day, however, while we are obliged to admit a very material percentage of recurrence, scarcely any surgeon of experience questions the advisability of radical removal of the entire axillary lymph apparatus and the execution of the other details of the Halstead method.

Kraske, Schwartz, Edebohls, and others have taken the initiative in a similar direction in their operations for cancer of the rectum; but we regret to say that their examples do not seem to have been very enthusiastically followed by surgeons in general, nor even by rectal surgeons, if we may judge by the recent textbooks of Tuttle, Gant, and Matthews.

The importance of this subject is apparent to any one who has in charge a case of cancer of the rectum; but to those who have not, a few statistics may be of interest. About 5 per cent. of all cancer is located in the rectum, and over 6 per cent. in the rectum and sigmoid. Of all intestinal cancer about 80 per cent. is in the rectum.

Of the cases of rectal cancer only about 7 per cent. are at the anus, and 26 per cent. in the infraperitoneal portion of the rectum, while 67 per cent. are in the supraperitoneal portion of the rectum. These figures, compiled from many sources by J. P. Tuttle and others, show this condition to be much more prevalent than one would at first suppose, and if Roswell Park's statement that statistics show cancer to be rapidly on the increase is true, the subject must of necessity grow in importance.

We have not up to the present time any very pleasing statistics to quote as to the results of operative treatment of cancer of the rectum, yet it is true that even the imperfect methods of the past have proven vastly superior to a palliative or "let alone" policy. The average case of cancer of the rectum proves fatal within one year unless it is operated upon. The average life after *successful* operation is two years and a half, while the primary death rate is about 20 per cent.

Assuming the three-year limit without recurrence to mean cure, Hupps' table, made up from the records of various operators, shows that about 15 per cent. are cured. Tuttle reports that, counting a *four-year* limit as a cure, his own records show the ultimate recovery of 21.8 per cent.

Various operators have reported many cases which have been traced for long periods and found still free from recurrence: Cripp, one case, twelve years; Quenu, one case eight and a half years; Boeckel, one case eight years; Kocker, one case, each ten, fourteen, and sixteen years.

From these figures we can draw at least some solace and look hopefully for the results of a more perfect procedure.

We do not believe that a radical technique has been generally adopted, and it is with the desire to add even a little to the definition of this subject that we take the liberty of reporting in abstract two cases previously reported, and a third, as yet unreported, in which we assisted a friend to operate; also to record in as detailed a manner as we may, an operation which was conceived independently, but which corresponds very closely with the previously published method of Schwartz.

More mature experience and thought have led us to modify somewhat the technique reported in the paper above referred to, and it seems that the technical modifications are so vital that they warrant description at this time.

Analysis and comparison of the various operations which have been and are commonly executed for the radical or palliative treatment of cancer of the rectum, would necessitate a monograph upon the subject, and we therefore refer anyone deeply interested to the recent exhaustive treatise of Quenu and Hartmann and the writings of Kraske, J. P. Tuttle, Matthews, and others. We wish to make, however, this general statement: that each of these methods has some very objectionable features. The majority of them are incomplete in that they deal mainly with the primary growth from below, necessarily ignoring the lymphatics which converge in the sacral hollow very much as the lymphatics from the breast converge in the axillary space, even to its apex.

Many of these methods attack the growth by the posterior route. This results in a bloody and difficult operation, with little better access to the growth than the perineal route, and no opportunity to inspect and remove the sacral lymphatics.

In our opinion, only those methods in which the abdomen is freely opened from above are, in this day of surgical progress, worthy of our attention, and we believe that careful pathological research will demonstrate this fact, as it did in the case of W. B. S., an abstract of which is submitted herewith. Of this class of operations the newer method of Kraske, by the abdomino-sacral route, is unnecessarily severe and bloody, and is weakened by an attempt to preserve the anus, which in many cases must cost the patient his life.

The operation of Schwartz has the serious drawback of a left lateral incision, which must of necessity give rather poor access to the deep pelvis, and again attachment of the gut to the parietal peritoneum is not, in our experience, necessary.

The technique, a description of which follows, has been somewhat modified with each successive case, and there is doubtless room for further improvement. No claim of priority is made, for over twenty years ago Volkmann foreshadowed, in his writings, the general principle upon which it is based, while Edebohls, in the *American Journal of Obstetrics*, August, 1901, reported a somewhat similar procedure, and Schwartz in November, 1898, executed practically the same procedure, except that his incisions were less favorably located.

Operation.—The patient is prepared in the usual manner pursued in our laparotomy cases, which consists of a diet of animal food exclusive of milk, large quantities of water, rest in bed, the avoidance of catharsis, the rectum being emptied by enemata and the field prepared by a method which does not differ materially from that in general use.

The patient is placed in the Trendelenburg posture, and a liberal median incision into the abdomen is made. The liver and other abdominal organs are inspected to determine the possible presence of metastatic growths, and if such are found the operation had best be abandoned in favor of colotomy or some other palliative procedure.

The rectum and sigmoid are now inspected to determine the extent of their involvement. The sigmoid and descending colon having been somewhat pulled down toward the pelvis, the whole upper abdomen is isolated from the field of operation by means of bolsters and gauze packing.

We now proceed to make an artificial anus somewhat after the method of Witzel, as follows: An incision one and one-half inches long, parallel with

Poupart's ligament, and extending through the external oblique, is located somewhat internal to the left anterior superior spine of the ilium, the edges of this incision having been widely retracted, the opening into the abdominal cavity through the internal oblique, transversalis, and peritoneum is completed after the manner of McBurney's appendical incision by separating the fibers rather than cutting them.

Two inches below this and parallel to it (about one and a half inches above Poupart's ligament) a similar incision is made through skin only; dissecting now from one to the other in the subcutaneous cellular tissue, a bridge of skin is raised under which the gut terminus is to be drawn.

We now select about the highest point on the sigmoid (at least four inches above appreciable cancer) which can be drawn out through the upper incision, down under the skin bridge and out at the lower opening; all this is a matter of approximate estimation. The mesentary of the sigmoid at this point is now transfixed by two pieces of coarse silver wire, the gut is milked free of pieces, the pieces of silver wire encircle it near together, and each is twisted down hard. The gut is now divided between the wires, and the mucous membrane of each end thoroughly cauterized with the Pacquelin. The scissors or knife used for this incision are isolated from the other instruments and the field carefully disinfected. A forceps passed through the lower skin incision under the skin bridge, through the upper incision into the abdomen grasps the terminus of the gut and draws it to the skin surface.

This portion of the operation is now abandoned, unless it should be found necessary to liberate the mesosigmoid in order to approximate the gut terminus to the lower skin incision. In this case the liberation is effected by slightly nicking the peritoneal layers of the mesosigmoid without injury to the vessels lying between them.

If it chance that this intestinal section is at a point where the blood supply comes from branches of the sigmoid, as is usually the case, we proceed at once to ligate the mesentery in sections downward toward the pelvis and backward toward the spine, till an open space is reached between the branches of the sigmoid artery and the superior hemorrhoidal. As this part of the operation proceeds, the upper end of the rectal segment is gradually drawn toward the lower angle of the incision. Now, with a pair of long-handled scissors, the right peritoneal layer of the mesosigmoid and mesorectum is incised, extending down beside and close to the gut to the point where the gut disappears into the floor of the pelvis; here the incision passes around the gut anteriorly and toward the left between it and the vagina in the female, and the base of the bladder in the male. This incision is now met by a similar one of the left layer of the peritoneum forming the mesosigmoid and mesorectum.

Lying between the two incisions, back of them, and underneath the flaps which will be formed by dissecting up the peritoneum in an outward direction on each side, is a mass of loose areolar tissue, fat, sacral lymphatics, the superior hemorrhoidal artery and its branches, and little else; working back into this areolar space, after having lifted up somewhat the peritoneal flaps formed by these incisions, we easily reach the superior hemorrhoidal, where it passes over the promontory of the sacrum and find ourselves in a nest of lymph nodes.

The artery is ligated and cut short, thus controling practically all the circulation of that portion of the rectum with which we deal from above. Pulling the rectum now still further forward with blunt scissors and the fingers, we are able to clean out the entire sacral hollow from the promontory downward, leaving all the questionable tissue attached to the rectum as a shaggy mass. This dissection is continued downward quite a distance below the disappearing point of the rectum in the floor of the pelvis.

The incisions at the side and in front of the rectum are somewhat deepened, and the blunt dissection continued until the whole organ is isolated down to the rigid pelvic floor.

The most gratifying part of all this procedure is the ease with which it can be accomplished, and the absolute freedom from hemorrhage after the ligation of the superior hemorrhoidal artery.

If the operation is on the female subject, the vagina having been thoroughly prepared before beginning, the assistant passes a uterine dressing forceps into the vagina, making its blades prominent in the posterior cul-de-sac. We now cut through into the vagina from above, place the proximal end of the rectal segment in the blades of the forceps and start the process of drawing the rectum into the vagina. If, on the other hand, the subject is a male, we reverse the position of the rectum, carrying its superior end down to the very bottom of our posterior dissection, where it is abandoned. In other words, in the female the upper end of the rectum now forms the anterior limb of a loop ending in the incision into the vagina, while in the male it forms the posterior limb of a similar loop ending near the coccyx.

The whole mass of rectum and excised tissue is now dropped into the pelvis, the peritoneal flaps are drawn up over and across it and quickly sutured together with fine catgut. We find that these flaps easily approximate and serve to isolate completely the field of the balance of our operation from the abdominal cavity.

The abdominal portion of the operation is now complete, and we proceed at once with the toilet, the covering over of any raw surfaces and the suture of the abdominal wound in layers according to our usual custom.

A temporary dressing is applied, the patient is placed in the lithotomy position, and from this point on our procedure must vary with the sex of the patient.

Approaching the field of operation from below, in woman the forceps passed through the vagina is attached to the upper end of the rectum, just entering the short incision made from above. We proceed at once to cut from this incision downward exactly in the median line, thereby splitting the perineum straight back to the rectum. As the incision on to the skin surface of the perineum approaches the anus, it divides to encircle it. Retractors are now introduced, the perineum pulled well apart and the lower end of the rectum freely dissected out. If the light is good and the assistants make proper retraction, there is nothing to hinder cutting boldly, rapidly, and wide of the growth, removing the whole mass with very little danger of soiling the wound.

This having been accomplished, the perineum is restored with catgut and silk-worm gut sutures, a small gauze drain having been left in the upper end of the vaginal incision, while the dependent anal wound is left slightly open.

In the male, on account of the proximity of the bladder, urethra, prostate, and seminal vesicles in front, it is better to approach the rectum from behind. This is done by means of an incision

encircling the anus and extending up the median line posteriorly nearly to the tip of the coccyx. This incision is deepened, and we begin the isolation of the rectum from below after having occluded its anal end with either forceps or a ligature. It is not at all difficult to carry this dissection up to a point where we break through into the pelvic fossa and meet the upper end of the isolated rectal segment which we had deposited in the depth of the pelvis.

We have followed the plan of executing this procedure in the lithotomy position. It is possible, however, that a lateral or semi-prone position would be more convenient.

It has not as yet been nccessary to extend the posterior cut as far as the tip of the coccyx. There is no reason, however, why it cannot be extended considerably higher by going to the left of the coccyx as recommended by Kraske and many of the French and German operators.

The completion of the removal of the entire mass through this incision is very little more difficult than in the female; and in the cases which we have observed, the hemorrhage has been neither very profuse nor difficult to control.

The entire mass, having been finally removed from below the wound, is largely closed by means of three or four deep sutures—an opening having been left for drainage.

The completion of the artificial anus has in our cases been determined somewhat by the condition of the patient. If the patient is in a precarious condition (and the operation is necessarily a protracted one) it is not absolutely necessary to spend much time over the careful adjustment of the artificial anus, and it might be wise to leave this matter until the final stage of the operation. We have completed the artificial anus by merely introducing about ten catgut sutures to attach the intestinal terminus to the skin at the lowest lateral incision, and have sutured the skin of the upper incision.

It is a waste of time to sew the intestinal to the parietal peritoneum. We have been in the habit of using an occlusive dressing for our median incision, thus preventing its contamination from the artificial anus. Should it seem desirable to introduce into the abdomen a saline infusion, it can be easily done through the upper lateral incision after the perineal work is completed.

Case I—Mrs. R., aged forty-seven, multipara. Family history negative as to cancer; lost right limb by amputation for tuberculosis of the knee at the age of thirty-two; was operated successfully for procidentia by the writer (amputation of the cervix, perineorrhaphy and ventrosuspension). Has had bloody stools for some months. Examination revealed cancer, extending from within an inch of the anus to a point beyond the reach of the examining finger.

Operation, January 10, 1902, as described above, except that the abdomen was not closed till after the vaginal work had been completed. Result: Apparent complete recovery, marked gain in general health, excellent control of both gas and fæces by means of a hard rubber cup and bandage.

Conclusions.—(1) The accepted methods of operating for cancer of the rectum correspond in lack of thoroughness to the old-fashioned amputation of the breast, supplemented by removal of a few enlarged lymph nodes from the axillary space. This operation has been supplanted by the superior technique of Halstead and a more radical method of dealing with cancer of the rectum, which n cludes removal of the sacral lymphatics, is indicated with equal clearness. (2) In very few cases of rectal cancer indeed is it possible to remove completely even the primary growth from below, for it appears that many inches above the ending of the macroscopic growth cancerous tissue is still found in the mucous membrane (case III). We cannot conceive of the complete removal of the infected glands from the sacral hollow by any of the vaginal, perineal, or sacral operations. (3) While no one should underestimate the misfortune of an artificial anus, it should be remembered that sphincteric control is frequently lost after severe rectal operations, even though the anus is preserved, that in this case the opening is very disadvantageously located for mechanical control, and that an artificial anus constructed as above described is practically perfect. (4) We believe that in the vast majority of rectal cancers the above—or some equally radical procedure—should be executed if the patient is to receive the benefit of modern, instead of obsolete, surgical principles. (5) This procedure presupposes a perfect surgical technique, and rapid but painstaking work, and especially would we emphasize the great importance of completing the abdominal work before attacking the perineal portion of the operation.

Case II—Mr. L., aged forty-two, American, pianopolisher. Father died of consumption, aged forty years; mother of Bright's disease, aged thirty years. No previous illness, always well and strong. One year ago was attacked with diarrhœa, which has continued ever since, always accompanied by considerable gas. Bloody stools for many months. Marked pallor and emaciation. Examination with the proctoscope shows a large indulated mass upon the rectal wall, about four inches from the anus and extending upward three or more inches.

Operation, May 5, 1902, under gas and ether. Time, three hours and ten minutes. Infusion salt-solution one pint. In this case the sigmoid was brought out just above Poupart's ligament, and the anus located upon the anterior surface of the thigh. Reoperated on September 18, 1902, for change of position of anus from anterior surface of the thigh to the abdominal wall. Present condition: Good control of gas and fæces by means of a cup and bandage. Gain in flesh, able to work, and appears perfectly well.

Case III—Mr. W. S.. aged forty years, American engineer. Operated upon by Dr. E. G. Tuttle, assisted by the writer. One year ago noticed an itching about the anus. One month later diarrhœa developed three to four times a day. Two months later blood appeared in the stool and pain of dull aching character in rectum extending to pubes. This has continued, and patient lost twelve pounds.

Operation, October 9, 1902. Time, three hours and twenty minutes. Stimulation with strychnine. Died October 12, 1902, of septic peritonitis. Autopsy shows perfect healing of the peritoneal flaps with perfect condition of the gut terminus. While Dr. Tuttle was the operator, the writer assumes a share of the responsibility for the infection, because owing to the extremely bad condition of the patient we were obliged to disarrange somewhat the usual orderly technique and both work as rapidly as possible.

Pathological examination by Dr. W. H. Dieffenbach: (1) Glands five inches from anal orifice. These were found to be carcinomatous. (2) Glands six inches from anal orifice. These were also found to be carcinomatous. (3) Mucous membrane eight inches from orifice, contained cancer

neses. (4) Mucous membrane eleven inches (about sixteen inches in the fresh state) from orifice, contained cancer nests filled with cylindrical cells.

This last section was but one inch from the extremity of the intestinal excision.

The top of the specimen, mucous membrane and glands, showed no carcinomatous change.

A CASE OF ADENOIDS WITH MALARIA.*

By WALTER F. CHAPPELL, M.D.,
NEW YORK.
SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL, THROAT DEPARTMENT.

Some interesting symptoms which developed in one of my patients, after an adenotomy, leads me to make this report. A full history of the case is as follows:

M. T., girl, healthy at birth; but one month later symptoms of nasal obstruction made their appearance and increased until they interfered with her feeding and sleeping. The weight at four and one-half months was sixteen pounds. She was unusually pale, but otherwise seemed well.

On September 18, when she was five months and eight days old, I removed ten small pieces of lymphoid tissue from the nasopharynx without anesthesia. The following day she was very bright, and gained eight ounces the first week after the operation, four ounces in the second week, and three ounces the third week.

On October 4, a little over two weeks after the operation, she became fretful and irritable in the evening, and continued so each evening until the sixth, when she was restless the entire night. On the morning of the seventh the temperature was 105° F. In the afternoon I visited the patient and the temperature had then fallen to 100° F. The strength of her feedings was now reduced, but no diagnosis was made. A member of the family reminded me at this time that a sister of this baby had her adenoids removed when six months old, and that two weeks later she also developed a temperature of obscure origin. It was also suggested that the removal of the adenoids in both cases might in some way account for the temperature. I, of course, gave the suggestion every consideration, and examined the pharynx, nasopharynx, and every part of the upper air tract. The results were negative. The glands of the neck were also examined, as I thought an acute infection might have occurred without any evidence in the pharynx.

On the morning of the eighth the temperature was 100° F., but in the afternoon she became drowsy and the temperature rose to 105.3° F. The family were in the country, and I advised over the telephone their return to the city, which they did the next morning. I again examined the child very carefully, with a lingering suspicion that some infection might have taken place from the nasopharynx. Nothing local or general could be discovered excepting a slight enlargement of the spleen. This, with the sudden elevation of temperature and its rapid fall, made me suspicious of malaria. Further inquiries developed the following interesting facts:

The family had spent every summer in the same locality, and one of three children had developed malaria. The mother, who is unusually intelligent in matters pertaining to her children, had been cautioned against allowing the little ones to be bitten by mosquitos, and to avoid this she made a special effort to procure very fine nettings to protect the baby, and is absolutely confident that it was not bitten during the summer. On September 23 an older brother had a birthday party, and in the excitement attending the entertainment the netting covering the baby was disarranged, and the mother found a mosquito biting the baby on the right cheek. Two bites were found on the same cheek, but only one mosquito was seen. The bites were unusually severe, and were apparent two weeks later. The time between the bites and the appearance of the temperature, being about the accepted period of incubation of malarial fever, was considered an important link in the diagnosis. Blood was taken from the left ear on the evening of the ninth, and on examination showed anæmia, leucocytosis, and plasmodia malaria of the tertian variety. Bisulphate of quinine was begun at once, six grains a day both by mouth, rectum, and inunction. This was continued for a week with some benefit. On October 17 the temperature rose to 104.3° F. Dr. Holt was called in consultation and confirmed the diagnosis, and advised doubling the dose of quinine by mouth, and discontinuing the other administrations. A pronounced chill occurred the same evening, during which the patient became blue and shook violently. The following table of the highest and lowest temperature in twenty-four hours gives also the amount of quinine administered in that time, and shows how it was increased until the maximum dose of twenty grains was reached:

Date 1902.	Highest temperature in 24 hrs.	Lowest temperature in 24 hrs.	Amt. quinine by mouth in 24 hrs.

Total amount quinine in 27 days ..... 241 grs.

After the large dose of quinine the temperature rose only once above 100° F., and there was a general improvement in all the symptoms. A blood examination made on the 23d of October showed polymorphonuclear leucocytosis and pigmented leucocytes, both indicating recent malaria. The quinine was given in four-grain doses one hour before the feedings, and was vomited only six times, a second dose being repeated immediately when this occurred, and was always retained. The food was rejected eight times and I believe was due more to the malarial poison than to the quinine. No unpleasant symptoms developed from the quinine, excepting possibly some restlessness on the night of the 27th

*Read before the Pediatric Section of the Academy of Medicine.

of October. The loss in weight between October 8 and November 2 was twenty-two ounces. On November 4, two days later, an increase in weight began, and during the following week there was a gain in weight of nine ounces. The quinine was discontinued on the 6th of November, and up to the present time there has been no return of malaria.

Remarks.—This case has many interesting features for laryngologists and pediatricians. The early appearance of lymphoid tissue and its rapid growth and extreme anæmia are unusual in so young an infant. High temperatures occasionally follow operations on the throat, especially those of the nasopharynx, but they are usually the result of staphylococcic and streptococcic infection, or the forerunner of some contagious disease. From whatever cause, it is very apt to be attributed to the operation if it occurs soon after. I confess a malarial infection in so young an infant was an experience for me, and the early diagnosis saved me considerable anxiety and relieved the operation from any responsibility. The amount of quinine taken without unpleasant consequences was also a new experience.

The knowledge of the exact date of the mosquito bite, and the appearance of the first malarial symptoms ten days later, fixes pretty definitely the period of incubation of malarial fever. As a matter of interest, and to complete the circumstantial evidence as to the method of infection, I procured thirty mosquitos from the locality where the family resided during the summer, and out of this number three of the malarial bearing variety were found.

7 East Fifty-fifth Street.

Acute Paresis.—Stewart Paton and G. L. Rusk report a case, giving its clinical history and pathological findings. It is probable, they say, that cases of acute paresis are of greater rarity than has commonly been supposed. In order to form an accurate judgment as to whether a given case may be grouped under the *forme foudroyante*, it is not only essential that the subacute or chronic initial period be excluded by the history of the case, but the acuteness or chronicity of the pathological process in the central nervous system must be carefully considered. The pathological findings reveal nothing that is essentially characteristic of the disease, although there has been noted in particular a new cell alteration which is in a sense pathognomonic. There is a general and not a localized disappearance of fibers from all cortical areas, the neuralgia shows an increase of the cellular elements, particularly of the large size spider cells with but little, if any increase in the fibers. The blood vessels, particularly the larger arteries of the cortex, are well filled with blood. Many round nuclei are found in the perivascular spaces. In most of the cortical areas numbers of plasma cells are present. They have not been found in the tissue surrounding the vessels. The character of the changes in the various organs, as well as in the central nervous system, suggests a general intoxication. The vascular changes of the cortex are not sufficient to account for the degeneration of the nerve elements.—*The American Journal of Insanity.*

Contagious Insanity.—Georges Carrier holds that insanity is communicable under certain conditions, the insane person being possessed of stronger will and possibly a stronger intellect than the persons who become insane through his influence. The latter are from heredity or disposition open to suggestion as it were, and are passive agents. There are three forms of this contagious insanity; first, that which is *imposed* by incessantly repeated morbid suggestion, the passive agent never originating any delirium or hallucination, but simply repeating those of the active agent, his insanity disappearing when the suggestive element is quiescent. The second form is *simultaneous* insanity, occurring at the same time in two persons intimately connected with each other. The morbid suggestion acts by some inter-mental process and by unconscious imitation. The third form, *communicated* insanity, is characterized by the fact that the passive subject while under the influence of the active subject yet has hallucinations which reflect his own individuality. Persons having this unfortunate effect upon each other should, of course, be separated.—*Archives de Neurologie.*

Dermatoses of the Insane.—James MacFarlane Winfield reports the results of his investigations made to determine whether the mentally unsound are more or less afflicted with dermatological diseases than those in full possession of their mental faculties. Over a thousand patients in the Long Island State Hospital for the Insane were examined. It was proved that the skin shows less tendency to disease when people are obliged to live regular and well-ordered lives. Of these patients, nearly all of whom were from the lower walks of life, there were only 146 examples of pure skin disease, and some of this number were from external causes, or had been contracted before entering the institution. The examination has also demonstrated the fact that the insane are more subject to degenerative dermatosis than those mentally sound. It is further evident that many of the statements of the alienists, so often quoted and reiterated regarding the cutaneous stigmata, are entirely wrong, doubtless because founded on insufficient basis.—*The American Journal of Insanity.*

A Series of Cases of "Non-septic" Puerperal Pyrexia.—J. Lamond Lackie records a number of cases in which there was decided puerperal fever, without septic infection. In one the condition was entirely neurotic and the high temperature entirely disappeared under moral treatment alone. In another the cause was influenza, the patient having evidently been infected by the nurse. Appendicitis was the cause in a third case, but was not diagnosed at the time. The patient had a second attack later. Scarlet fever and diphtheria were responsible for two cases of hyperpyrexia, and in another case the sole cause of the alarming temperature and symptoms, even to the extent of delirium, was retention of urine, both physician and nurse having been misled by the fact that the patient passed a certain overflow of urine a regular intervals, not by constant dribbling, as is more frequently the case. Other puerperal fevers not due to septic infection may be caused by acute constipation, chill, emotion, congested mammæ, sore nipples, or reflex irritation.—*Edinburgh Medical Journal.*

The Preparation of the Patient for an Operation and the Relative Value of the Blood Examination.—A. E. Benjamin considers that the necessary preparation of a patient for an operation is too often neglected and that the time is frequently too short. The general state of the patient before operation is as important as the pathology of the local disease present. Many post-operative complications arise that could be avoided by proper preliminary treatment. The leucocyte count and hæmoglobin estimate should be employed as an aid to diagnosis and as a basis of treatment in surgical cases before operation. By the blood examination we may be able to confirm our diagnosis made from clinical symptoms, or we are able to make a diagnosis of concealed pus when not determined otherwise. We may save our patient's life by delaying the operation until the per cent. of hæmoglobin reaches a safe standard or the white count reaches nearer the normal line. We may be justified in operating at once in a case where the white count is rapidly rising or the hæmoglobin is gradually falling.—*Northwestern Lancet.*

THE FUNCTIONS OF THE DUCTLESS GLANDS.

DR. C. E. DE M. SAJOUS, whose views on the functions of the ductless glands have been widely quoted, bases his arguments on the assumption that there is an affinity of adrenal extract for oxygen, and that it is the carrier of oxygen to the tissues, whence follows the erection of the adrenals into a position of commanding physiologic importance. The oxygen-laden adrenal extract, termed *adrenoxin*, is identical with the "oxidation ferment" found in the plasma by several observers, and with the Lepine's "glycolytic ferment." Oxygen travels via the plasma through various unrecognized plasma channels, *e. g.* the hollow, tubular "axis cylinders" and the dendrites of the nerves, and in the neuroglia fibrils, which are plasma capillaries, and which contain a fluid identical with plasma in staining reactions. The immanent source of all nerve energy is the reaction between the myelin surrounding these plasma tubes and the contained plasmatic oxygen. In the muscles, the myosinogen represents the contractile substance which, upon combining with the oxygen of the plasma, liberates energy of contraction, the function of the nerves being merely regulative. Fluctuations in the temperature of the blood are due to variations in the amount of its fibrinogen, which combines in fixed ratio with the plasmatic oxygen. The adrenals are connected with the anterior pituitary body via the solar plexus, splanchnics, and the cervico-thoracic ganglion. This pituitary body is the most important organ in the economy, being the governing center of the adrenals, and, through them, of all oxidation processes. The efficiency of this pituitary body is maintained through thyroid action, the stimulating principle being the thyroidal iodine compounds. Instead of being due to a direct action on the blood or cellular elements, "symptoms of infection or poisoning are all manifestations, more or less severe, of *overactivity or insufficiency of the adrenal system.* Indeed, *the physiological action of remedies was also traced to the anterior pituitary body.*" Cholera, cholera infantum, and poisoning by arsenic and by toxalbumins, and the intoxications, are all "syndromes due primarily to adrenal insufficiency." Pulmonary tuberculosis is due primarily to lowered adrenal function, and all the remedies for it are adrenal stimulants. Syphilis, too, is due to adrenal insufficiency, and mercury is a powerful adrenal stimulant, and iodine is "nature's own stimulant." The majority of drugs, toxins, and physiological toxalbumins stimulate the adrenals in small quantities, and paralyze them in larger amounts. In tetanus, epilepsy, hydrophobia, septicæmia, and eclampsia, sedatives and depressomotors may easily do harm by depressing adrenal action, and the success of Baccelli's carbolic-acid treatment of tetanus and of the Pasteur treatment of hydrophobia by injection of extract of desiccated cord, is owing to stimulation of the adrenal system. The element of specificity in each disease is an expression of the particular way in which each drug or toxin affects the adrenals, some stimulating first and then paralyzing; others, like hydrocyanic acid, overwhelming them at once. The posterior pituitary body is the chief functional center of the nervous system. It is the anterior pituitary body's co-center in sustaining metabolism, and it is an important feature of the morbid process in influenza, hay fever, hysteria, catalepsy, and other obscure affections. The spleen and pancreas unite in furnishing trypsin to the blood. Its main function in the blood is the destruction of toxic albuminoids. Phagocytosis is the preponderant immunizing factor, but it is trypsin which reduces the toxic albuminoids to inert cleavage products in the digestive vacuoles of the leucocytes. Ehrlich's views become simplified, his amboceptor being adrenoxin, and his complement (Buchner's alexins, Metschnikoff's cytases) being trypsin. Fibrinogen, however, plays a preponderant rôle also in this matter, the process requiring the coöperation of the three factors, trypsin, adrenoxin, and fibrinogen, for trypsin is sufficiently active only in the presence of given proportions of adrenoxin and fibrinogen. Thus in typhoid fever, fibrinogen is missing, whereas in diphtheria, it is trypsin which is lacking in the blood, and the dominant active principle of diphtheria antitoxin is trypsin. The white blood cells have functions exceeding in importance those heretofore ascribed to them, even hypothetically. The neutrophiles are traced from the solitary and agminated follicles to the cavity of the intestine, where they ingest proteids; and through the villi, and the mesenteric and portal veins where they absorb trypsin. They form peptones, myosinogen, and fibrinogen, and distribute these to all tissues, the muscles, and the blood itself. The eosinophiles are daughter cells of the neutrophiles, mitosis occurring in the liver. They are traced to the pulmonary alveoli, where they participate in the formation of the nucleated epithelium. Their product is hæmoglobin. The basophiles take up fat and change it into myelin, which they distribute to the nervous system. Altogether, the views expressed are sufficiently at variance with received opinion to attract attention.

SEWAGE POLLUTION NEAR NEW YORK CITY.

THE Geological Survey of the Department of the Interior of the United States has recently published a manuscript relating to sewage pollution in the metropolitan area, written by Mr. Marshall O. Leighton. The question of uncontaminated water for domestic use is one that concerns the United States very intimately, for owing to carelessness or to the use of unscientific methods of providing a pure water supply, the large cities and towns of this country are, on the whole, far behind those of Europe in this

respect. Some American centers of population, in fact, are notorious for their defective water, and are in consequence continually suffering from disease brought about by their short-sighted policy. Other cities have been taught by bitter experience how fatal it is to neglect the best known means of ensuring as pure a water supply as possible.

Mr. Leighton points out that in this age of commercial and social progress, eventually the public sewer is laid to the nearest and most convenient body of water, and that in the course of time in inland municipalities there may be developed a system of sewerage conducting such a volume of city waste that the largest river on the globe cannot dilute it sufficiently to disguise its presence. Further, the belief that a polluted river will purify itself in the course of some miles is growing dim, and it is becoming daily better understood that for household purposes water must be purified, and that for the sake of the health of the community at large extensive pollution must not be permitted in the vicinity of dwellings.

Mr. Leighton in his paper considers the matter from a standpoint of diminution of natural resources with special reference to the rivers in the "metropolitan area," comprising northern New Jersey, southern New York, and the western part of Massachusetts. He takes into account the water resources of this section, and shows, as closely as available information will permit, the loss which has come about by reason of river pollution.

Among the rivers of New Jersey the drainage system of the Passaic takes the first place, and at any point in this river below the city of Paterson the pollution is very bad. The conditions all along the lower reaches are declared to have become insufferable. The Passaic Valley Sewage Commission, created by an act of legislature of New Jersey in 1896, concluded its report by saying that the pollution of the lower Passaic River appeared to be completely established as a public nuisance, an injury to health, and an increasing menace to property interests from the beginning of the Great Falls to below Newark.

The New Jersey State Sewerage Commission reported in 1901 that "the sewage pollution of the Passaic has during the last year increased in its evil effects. Heretofore the objectionable odors have been limited to the summer months, but during the last autumn the stench continued until the freezing water locked the foulness into the ice. The rainfall was below the average during the autumn, and wide spaces of sewage-befouled mud were exposed to the air, giving forth nauseating odors."

Mr. Leighton summarizes the damage done to the Passaic system by pollution as follows: (1) Abandonment of three water-supply intakes and the establishment of three others, at a total expense of not less than $20,000,000. (2) Extensive decline of power values because of inadaptability of water for use in boilers and in manufacturing processes. (3) Loss of annual harvest of ice weighing 10,000 tons. (4) Absolute destruction of fisheries in lower valley. (5) Impairment of realty values, the extent of which cannot be too highly estimated in view of the fact that similar properties in clean localities have been made of immense value.

With regard to the Hudson, Mr. Leighton says: "Pollution along the middle or navigable section above salt-water influence is unavoidable even if city sewage were entirely excluded from the river. In order to make the whole pure it would be necessary to close the river to commerce, and as its value as a means of transportation far overtops all other values which it may have, such a suggestion is manifestly absurd. We are forced, then, to conclude that, for the present at least, while pollution may unfit the Hudson up to Troy for use as a domestic water supply without filtration, the damage to the resources is insignificant compared to the damage which would occur by excluding sewage from the river. While the water remains fit for filtration, then, the middle Hudson is of more value as a polluted stream than it would be if preserved unpolluted. But if the time should ever come when the condition of the Hudson should approach that of the Lower Passaic, then it would be highly necessary to enforce sewage purification upon the towns and cities along the banks."

The eastern tributaries of the Hudson are but slightly polluted, but the western tributaries, which include its great western arm, the Mohawk, are subject to extensive pollution.

In the paper to which reference has been made, the writer clearly shows that in the case of the Passaic drainage system, the damage done to health, property interests, and value generally by pollution is very great, and the condition of that river calls for effective remedial measures, as well as pointing a moral.

As to the Hudson in its present state, the best known means of purifying water drawn from it for household purposes should be utilized, but otherwise matters had better be left in *statu quo*. As Mr. Leighton says: "The whole question has been modified by the successful introduction of filtration for water supplies. It is manifest that the most potent damage that is ordinarily done to the resources of a stream is its destruction for use as a source of water supply, but, having overcome this difficulty by the introduction of filters, it is more likely that the tendency will be toward toleration of a certain amount of pollution, and the expense of filtration will be regarded as a fixed charge upon the community at large."

Food Adulteration.

The *Yale Medical Journal* directs attention editorially to the report of the New Haven State Agricultural Station in which are given the results of analyses of various articles in common use as food and drink, which were purchased in the open market. The results are as follows: Coffee—of fifty brands examined, five were adulterated, mostly with ground peas and chicory; jellies and jams—of sixty-six specimens examined, only 19 per cent. were pure; tomato catsup—of ninety-four samples, 84 per cent. were colored with coal tar dyes, and 65 per cent. contained chemical preservatives; vanilla extract—of sixty-two samples, only one-fourth were pure; lemon extract—of sixty-six samples, only eight were pure; spices—of 216 samples, 70 per cent. were pure, etc. Of 375 samples of milk intended for sale to families, purchased in twenty-eight towns, over 8 per cent. were adulterated, and in many samples it was

found that chemical preservatives had been used, which is dangerous not only because of the direct action of the drugs, but also because of their being a substitute for cleanliness and sanitary precautions. The editorial continues: "The report gives the name of the brand examined, tells where it was purchased, how much it contained, and what it cost." This is valuable information and in some way or other ought to be brought to the attention of the consumer. It seems to us that our daily press might do more missionary work along this line than it is inclined to. We have seen but one notice of the last report of the Agricultural Station in any daily paper (The New Haven *Register*), and that does not touch the main issue—*i. e.* put the individual consumer in position to utilize this information to his own advantage."

Rural Depopulation of France.

In all civilized countries, there has been for many years a steady but progressive exodus from the country to the towns. The rural population yearly decreases, while the large towns grow more and more overcrowded. In Great Britain, this state of affairs has existed far longer than in any other country, but of late, both in Germany and France, there has been a flocking of the rural inhabitants to the towns. In France, however, in addition to this depletion of the number of country-dwellers by such means, there are other agencies at work which aid in reducing the rural population.

In an address before the Society of Arts of France, Mr. Cloudesley Brereton, in the Journal of that body (December 12), draws a striking picture of the rural life in France, which is commented upon by the *Westminster Gazette*. It appears that much the same causes operate to lead the countryman from his home in France as in other countries. The attractions of town life, higher wages, and conscription are among the most obvious explanations of the depopulation of the rural districts. But there are other causes, says the London *Journal*, which are giving the statesman and philosopher something to think furiously about. "The low birth rate is partly due to the high standard of personal comfort, and partly also to the system of inheritance. Mr. Brereton quotes the witty Frenchman who said that the English system of primogeniture confines the number of fools to one per family, but that the French have discovered a most effectual way of rendering the whole family imbecile. Mr. Brereton also casts a lurid light on the present condition of what was once the most temperate country in Europe, if not the world. The phylloxera was even a more terrible curse to France than was imagined when a Pasteur endeavored to stay its ravages. It made good wine dear. The poor were driven to beet-root spirit, absinthe, and to other horrors for their stimulant. We are told that a workman's breakfast consists of slices of bread floating in spirit. Even children are brought up on this "soup." The inevitable results are already showing themselves. The number of recruits unfit for service in the Northern Departments has increased sixfold; in some cantons recruiting of conscripts is practically impossible. Sixty per cent. of the males and 70 per cent. of the females of the lunatic asylums at Alençon are alcoholics." The above harrowing description of the condition of rural France, it is to be hoped, may be somewhat overdrawn, but it is agreed on all hands that the French are among the largest consumers of alcoholic beverages. The death rate of young children in France is appalling, and can be attributed to a large extent to the alcohol habit of the parents. It would seem now as if a vehement crusade against strong drink may be waged throughout the world.

Climate and Character.

Climate has an undoubted influence on the character. Persons take from atmospheric conditions and surroundings many of their mental attributes; they seem to absorb into their being something akin to the climate and environment. Those born and reared in a rugged, wild and bleak country are generally rugged, hardy and stern themselves, while those brought up in a rich, warm, and genial climate and surroundings are themselves usually of a generous, easy-going nature. The London *Evening Standard*, of a recent date, discusses the subject and says: "In lands of the sun, where the earth offers the necessities and luxuries of life almost without labor, man is sapped of energy, and leads a lotos existence. No effort is demanded of him, and the capacity to do dwindles within him. He lolls sensuously in the lap of nature, a materialist and without ambition."

A temperate, bracing climate is the most healthy, both for body and mind. The strong air imparts force of character as well as power of limb. No one is superior to atmospheric conditions; it affects all, though sometimes unconsciously. Investigations in schools show that pupils are able to do their best work when the weather is cold, calm, and clear. In large factories, it is stated that an unpleasant day will reduce the output by 10 per cent. Again, continued hot weather invariably brings forth a crop of crimes of passion, while the summer is also the season most prolific of suicide. Rain seems to exert a deterrent effect on crime, and fewer deeds of violence are committed on cloudy days than on bright ones.

Whatever there may be said to the contrary, the fact is undeniable that climate influences to a remarkable degree character and conduct.

Regulating the Practice of Medicine and Surgery in Indian Territory.

An act to regulate the practice of medicine and surgery in the Indian Territory has passed the House of Representatives, and is now before the Senate of the United States.

The principal points in this bill are that after its passage no person shall practise medicine and surgery, or either, as a profession, in the Indian Territory, without first being registered as a physician or surgeon in the office of the clerk in the district in which he or she offers to practise. That to thus register the individual must file with the proper official a certificate of qualification, signed by a majority of the board of medical examiners of the district in which he or she is desirous to practise. That immediately after the passage of this act the United States judge of each district in the Indian Territory shall appoint for his district a board of medical examiners, consisting of three persons who shall be citizens of the district and graduates of some reputable medical college recognized by either of the American medical college associations, and who shall thereafter be duly registered under the act, and who shall hold their office for a period of four years, or until their successors are duly appointed or qualified. Another provision of the act reads, "that no person desiring to practise medicine shall be excluded on

account of any particular system or school of medicine that he or she may desire to practise."

Section 12 provides that all physicians and surgeons holding diplomas desiring to practise the science of medicine and surgery in the Indian Territory shall submit the same to the board of examiners for the district in which they desire to practise for examination and approval, for which said applicant shall pay a fee of one dollar to said board, and, upon approval by said board of said diploma, shall not be required to undergo examination. Any person violating the requirements of this act, upon conviction, shall be subject to a substantial penalty.

The Indian Territory has been for long a happy hunting-ground for adventurers of all kinds. It is therefore just that an act of the above description should be passed, in order that the most flagrant specimens of the medical adventurer should be excluded.

Migraine and Obstipation.

Among the causes of hemicrania the hereditary neuropathic handicap plays a great rôle, and Möbius regards the disease as a form of inherited degeneration. Haig incriminates uric acid, which is supposed to produce cerebral ischæmia. Others have brought forward psychic overstrains and excitements, and in young girls have pointed to menstrual disorders. In Schilling's series none of these factors were present; grandparents, parents, and brothers and sisters were, as far as could be ascertained, healthy. The cause in all was habitual obstipation, or a tendency thereto, extending over months. By migraine is to be understood not an occasional headache, but attacks of severe and usually (even though not always) unilateral, frontal, temporal, or occipital (less often diffuse) headaches, connected with pronounced gastric phenomena (sickness, anorexia, and, above all, vomiting), and a slow pulse. As a marginal fringe, irritative, sensory, psychic, and ocular disturbances occur. The migraine of obstipation offers no uniform picture, on account of variation in the marginal fringe. In light cases patients complain of dull headache, disinclination for intellectual work, anorexia, bodily pressure and discomfort, and inclination to vomiting and vertigo. It is striking that the feeling of illness is increased during defecation (which is accomplished only by hard straining) and vanishes, as at a stroke, when the bowel has been emptied. The severer, and the true migraine, cases go to bed at night without eating much, get to sleep with difficulty, or waken after some hours with severe pressure, and wrenching or boring pains in the occiput or in the temples, soon involving the whole head, though remaining predominantly unilateral. Soon there is added violent vomiting of watery fluid and bile, which is followed by gastric pains and abdominal sensitiveness. The pulse is slow, and the patient tosses restlessly, moaning, on the bed. The abdomen is hard and tense, and occasionally individual coils of the intestine can be felt contracted. The urine is scant and dark. These attacks usually recur with greater or less intensity at irregular intervals during two or three days. Involuntarily one here thinks of fecal stagnation as the cause, and in a series of cases, before vomiting set in, Schilling found an increased excretion of indican. He also points out that Ebstein found albuminuria with casts during fecal stasis, which disappeared upon the relief of the latter. Further, the hemicrania disappears upon removal of the constipation, and recurs when the latter is allowed to return. Schilling uses antifermentatives (such as ammon. sulfoichthyol 0.1 or creosol 0.05) as well as purgatives, but especially the wet pack for the body and legs, so as to produce several hours' sweating, and he points out that Dirmoser also praised hydrotherapy in hyperæmesis gravidarum, which he regarded as likewise the outcome of intestinal autointoxication. For a permanent relief, physical and dietetic measures are, of course, to be employed.

Military Hygiene in the Tropics.

In the *Journal of the Association of Military Surgeons*, for January, 1903, Major H. P. Birmingham gives a number of practical suggestions on tropical military hygiene. The first point of importance is the recruiting, as about 50 per cent. of those who were invalided home or who died should never have been sent out. The number of immature youths from seventeen to twenty-one years, whose only hope for life lay in being transported home, was deplorable. The man of poor physique should be unhesitatingly rejected, this term comprising all not absolutely and unqualifiedly meeting the requirements as to chest expansion and general physical development, and particularly excluding the tuberculous whose death warrant is signed by sending them to the tropics. The prescribed relation of weight to height should be *de rigueur*, the slim and lanky, the excessively tall, and the obese, being rejected, as also those having weak hearts. The prematurely aged and the neurotic should likewise be rejected, as they furnish a large contingent to the hospitals, from which very few of them ever return to duty. With few, if any exceptions, the age limits should be twenty-five and thirty-five. Marked caries of the teeth or any skin affection should lead to rejection. Respecting clothing, as men naturally discard everything possible during the day, and yet require protection from chill during the night, Dr. Birmingham recommends for field service, trousers and shirt of khaki flannel, the trousers being connected with the shirt by the belt, passing through loops in each, its weight being thus supported from the shoulders through the medium of the shirt. The flannel must be of sufficiently fine quality to be non-irritant to the skin, otherwise itching and erythema result, which are liable to lead to the dreaded dhobie itch. The abdominal band is to be unqualifiedly condemned. A light woolen sack, and shoes of the proper fit, light weight, and fine quality, are essential. The headgear is of the utmost importance. The depressing, not to say paralyzing, effect of the tropical sun demands full and adequate protection for the head. A proper hat or helmet might be made on the lines of the average native hat, which combines lightness, protection for face and neck, and thorough ventilation. It should stand away from and should not be capable of being pulled down closely over the vertex. For camp or garrison duty the ordinary government clothing will suffice. Regarding dietetics, tropical life has a decided tendency to lower nutrition, and in many instances this tendency is augmented by a greater or less deprivation of the customary aliment. Despite much opinion to the contrary, to maintain health in the tropics one needs as much, if not more, and better food than at home. The diet should approximate as closely as possible the usual home fare, not excepting wine at meals if the individual is so disposed. The notion of the unsuitability of the albuminoids as a component of the diet is a fallacy. Only distilled, boiled, or carefully filtered water should be drunk, and all excesses in eating and drinking should be avoided. This is all that is required to keep the average man fairly well in the

tropics. He may, notwithstanding the foregoing precautions, contract amœbic dysentery, the one dread disease of the Oriental tropics, but in most cases he will not. The tropical diseases concerning military surgeons are, in order of frequency and importance, dysentery (amœbic and specific), malarial and yellow fevers, dengue, beriberi, cholera, and bubonic plague. Sprue or psilosis, Birmingham considers a condition liable to be grafted upon any depressing tropical disease, and not a distinct, morbid entity. "Diarrhœa," almost without exception, means catarrhal, amœbic, or specific dysentery. The prophylaxis of dysentery consists in the most scrupulous attention to food and drink, and the maintenance of the highest possible standard of health. The intelligence and thoroughness with which the prophylaxis of malaria is carried out depends largely on the surgeon. Non-effectiveness among troops from malaria has always been large. In the Philippines dengue was common and widespread; the mortality from it was *nil*. Beriberi was occasional. The plague need not alarm civilized troops, no American soldier having contracted the disease during Birmingham's two years in the Philippines, though the disease prevailed in the islands. In the Philippines cholera has been entirely confined to the natives and the Chinese. With due care and perseverance the health of our troops in the tropics will never seriously suffer.

News of the Week.

A Typhoid Fever Serum.—Dr. Allan Macfadyean of the Jenner Institute of Preventive Medicine claims to have elaborated an efficient prophylactic and curative serum for typhoid fever. It is prepared by injecting into animals a product obtained by crushing typhoid bacilli in liquid air. The intense cold of liquid air does not destroy the toxin but renders the bacilli so exceedingly brittle that it is comparatively easy to break them up by saturation. The serum obtained by repeated injections of these crushed bacilli is both antitoxic and bacteriolytic and is curative as well as protective.

A New Hospital for Contagious Diseases.—Ground has been broken at the foot of East Sixteenth Street in this city for the new hospital for scarlet fever to be erected under the authority of the Board of Health. The institution will cost about $250,000 and will accommodate 225 patients. The new building will relieve the congestion at Riverside Hospital, on North Brother Island, and at the Kingston Avenue Hospital, Brooklyn.

New Professors at Columbia.—At a recent meeting of the trustees of Columbia University, Dr. Livingston Farrand, adjunct professor of psychology, was made professor of anthropology and assigned to a seat in the faculties of philosophy and of Barnard College, and Charles A. Strong, was appointed professor of psychology with a seat in the faculty of philosophy.

The New Bellevue.—The architects who will draw plans for the new Bellevue Hospital, have been instructed by the board of trustees to preserve the exterior plan of old Bellevue as much as possible. For that reason the new building will face the East River. The building will have long wings to the north and south, in order to secure the sun's rays as much of the day as possible. The balconies outside the wards will be preserved. The main hospital building will probably be six stories in height, while the administration building, which will be separate and front on First Avenue, will be lower. The hospital will be constructed of brick with stone trimmings.

New Serum for Tuberculosis.—Professor Behring claims to have obtained a protective serum against tuberculosis by his method of jennerization. This consists in injecting cattle with cultures of human tubercle bacilli, which are little if at all pathogenic for the animals, but whose toxin acts like toxoid in stimulating the production of antibodies. He has found that the serum so obtained is efficacious in conferring absolute immunity against infection with bovine tubercle bacilli in cattle, and believes that a like immunity can be produced in the human species. He even claims that the serum is curative in the case of young children, though it would probably not be in adults.

Destruction of a Hospital in a Tornado.—During a wind storm which visited Townsville, near Brisbane, Queensland, a few days ago, the walls of one of the wards of the hospital were blown in and six of the patients were killed, many others being injured.

Health Statistics of Harvard.—The annual report of the Harvard University physician, Dr. M. H. Bailey, has recently been issued. From it, it appears that during the last academic year there were 5,388 cases of illness. This is little more than an average of one illness each year for each man in the university. Last year forty-eight men were forced to consult the college physician because of overwork. Ten of these cases occurred in May, when the men were studying for the final examinations. There were more cases of indigestion than of any other complaint.

Foot-and-mouth Disease.—This disease has been discovered in the herd of a cattle-dealer in Bedford, N. H. The outbreak is regarded with concern by the officials of the Department of Agriculture, for the cattle belonging to the affected herd were picked up in various parts of New England, and many other cattle that had been stabled with those discovered to be sick are now scattered throughout the State. The United States authorities have issued an order quarantining New Hampshire because of this discovery.

Bequest to Manhattan Eye, Ear, and Throat Hospital.—Mrs. Ann Augusta Thomas, widow of General Samuel Thomas, and her children, Mr. Edward R. Thomas and Mrs. R. Livingston Beeckman, have given $50,000 to the Manhattan Eye, Ear, and Throat Hospital to endow a ward of ten beds, to be known as the "Samuel Thomas Memorial Ward," in the proposed new hospital building for that institution. Announcement of this gift was made at the meeting of the Board of Directors yesterday by Dr. Walter F. Chappell.

Changes in the System of Instruction at the College of Physicians and Surgeons.—A plan is under advisement which will change very materially the course of instruction at present followed in the Medical Department of Columbia University. The new policy will closely follow the methods now used at the Johns Hopkins and Harvard medical schools. A committee on the revision of the curriculum is reorganizing the course. One of the first institutions to go is the system of quizzes which has been necessary in the past, owing to the failure of the college authorities to provide for adequate class-room reviews and recitations.

Mistrust of San Francisco.—The Mexican Government has declared a quarantine for the whole Republic against San Francisco, and vessels from that port will not be allowed to land passengers or cargo at any Mexican port until further notice. The

Minister of the Mexican Government who ordered the general quarantine said that he had information which satisfied him that bubonic plague existed in San Francisco as late as January last. The United States Marine Hospital Service and the health authorities of San Francisco report that there has been no case of plague in that city since December last, although there had been an average of one case every week for three years immediately prior to that time. The Mexican Government evidently attaches great significance to the fact that the health officers of the city of San Francisco and the State of California have been employing every means to conceal the existence of the plague on the Pacific Coast. The outbreak of the plague at Mazatlan, two months ago, is generally believed to have been the result of infection brought from San Francisco.

A Suspected Cholera Ship.—The Anchor liner *Karamania*, which arrived at this port last week from the Mediterranean, lost six of her passengers and crew during the voyage. The symptoms were of an unusual character, but were thought by the Health Officer of the Port to be suggestive of cholera. The passengers and crew were detained at quarantine and the vessel was fumigated. No deaths occurred after the arrival of the ship

Too Much Attempted Legislation for Nurses.—A third "nurses bill" has been introduced in the New York State Legislature. Unless the divergent interests come to some understanding before the hearing on these measures, the Legislature will doubtless refuse to grant any of the requests. These bills all have much of merit to commend them, but their various sponsors had best get together or registered nurses will not be officially recognized for some time to come.

New York State Medical Examinations.—The Secretary of the State Board of Medical Examiners, representing the Medical Society of the State of New York, reports as follows regarding the January, 1903, State medical licensing examinations: Total number of candidates, 103; successful, 75, or 72.8 per cent.; unsuccessful, 28, or 27.1 per cent. Of this number eight had previously passed in the medical primary branches. There was but one "honor" licentiate. Fifty-one candidates appeared for certificates of proficiency in the medical primary branches (anatomy, physiology and hygiene, chemistry). Forty-seven, or 92.1 per cent. of these were successful.

New York State Hospital for the Care of Crippled and Deformed Children.— Drs. H. A. Gates of of Delhi, N. Y., Grant C. Madill of Ogdensburg, N. Y., and Frank Walker Sears of Binghamton, N. Y., have been appointed as consulting surgeons to the New York State Hospital for the Care of Crippled and Deformed Children, at Tarrytown, N. Y.

Streer-car Colds.—At a meeting of the St. Louis Medical Society on February 28, Dr. Fayette C. Ewing read a paper on "Street-car Colds," and offered the following resolutions, which were unanimously adopted by the Society: "Recognizing the fact that many colds and diseases of the respiratory organs are acquired by riding in draughty, ill-ventilated, cold, and crowded street cars, wherein the element of time conspires to produce a prolonged chilling of the body, terminating in localized congestion and consequent respiratory catarrhal affections, it is hereby declared to be the sense of the St. Louis Medical Society that street-car officials should take measures for a more uniform and equable temperature in our cars, with protection against draughts, and especially in such cars as run far out into the suburbs, where passengers must sit still for an extended period of time. And it is further declared that such lines of cars as make long runs, compelling long-distance passengers to endure a temperature under 60 degrees Fahrenheit, be condemned as dangerous and a menace to the health of their passengers and their patrons, who are hereby warned to seek other means of conveyance."

Health of Troops in the Philippines.—The report of the chief surgeon of the forces in the Philippines, for the month ending January 15, 1903, gives the strength of the command at 22,580 men, present sick 1,480, giving a sick rate of 6.51 per cent. On December 15 last this rate was 7.30 per cent., and on November 15 last it was 7.96 per cent. There were 38 deaths during the month, an increase of 4 over the previous month. The deaths were divided as follows: Suicide, 1; tuberculosis, 1; typhoid fever, 2; malarial fever, 1; dysentery, 6; diarrhœa, 1; cholera, 18; other intestinal diseases, 2; all other diseases, 6. Nearly one-half the deaths were due to Asiatic cholera; and nearly two-thirds of these deaths occurred in Company B, of the 11th Infantry, stationed at Ormoe, island of Leyte, which lost 11 men from cholera in four days out of the 85 men in the company. Of the other three companies of the same regiment stationed at thesame post, one lost one man and the other two were unaffected. The outbreak in Company B was believed to be due to an infection of the food. The other six deaths from cholera occurred at four stations. During the month cholera was reported by army medical officers as existing in twenty-four towns garrisoned by United States troops, or in the immediate vicinity of their stations. These towns were scattered widely over the more important islands of the archipelago. The chief surgeon states that in view of the continued existence of a large number of widely scattered cholera foci, from which the disease may at any time be carried by the natives into districts hitherto uninfected or in which the infection has died out, the end of the present epidemic of cholera can hardly be hoped for before the end of the next rainy season. Continued experience with cholera in this division fortifies the belief that cholera infection is readily amenable to sanitary measures, including careful disinfection and strict quarantine. It is not possible, however, to cause the natives to carry out proper precautions or submit to the restrictions through which alone the disease can be controlled. In nearly every instance in which cholera has appeared among troops it has ultimately been possible to trace the outbreak to direct neglect or disobedience of standing sanitary orders. Smallpox is reported as existing in a number of towns in the vicinity of military stations; proper measures relative to vaccination have been taken. The rate of sickness from dysentery and venereal diseases continues high. Four deaths from beriberi, three in native scouts and one in a white soldier, occurred during the month. On January 15 there were 147 garrisoned stations in the Philippine Archipelago. On duty at these stations were 235 medical officers, 20 contract dental surgeons, 1,417 members of the Hospital Corps, and 40 female nurses. During the month, 31 volunteer medical officers were mustered out of the service, and the remaining 48 will terminate their service on February 1. This reduction of the medical force has been made possible through the decrease in the number of soldiers in the islands, and the concentration of the remaining troops into larger posts, where they can be attended to by a smaller number of medical officers.

Philadelphia County Medical Society.—At a stated meeting, held March 11, Dr. G. Hudson Makuen read a paper entitled "Speech-defect in a Case of Organic Disease." He reported the case of a man who from early life presented awkwardness in gait and in movements of the hands, with intention-tremor, exaggerated knee-jerks, staccato speech, and oscillation of the eyeballs on lateral movement, and in which marked improvement in speech was effected by means of systematic training and exercise. Dr. Orville Horwitz read a paper on "The Use of the Electrothermic Angiotribe in Lieu of the Employment of Ligatures in the Open Operation for the Relief of Varicocele." He reported a case in which the operation mentioned was performed with the instrument of Downes, and the result was in every way satisfactory. Dr. John C. Hemmeter of Baltimore read, by invitation, a paper entitled "The Rôle of Intracellular Catalytic Processes in the Pathogenesis of Malignant Neoplasm," in which he pointed out the inadequacy of existing explanations of the etiology and pathology of carcinoma particularly, and in turn suggesting the action of an enzyme as a possible provocative factor.

College of Physicians of Philadelphia, Section on General Medicine—At a stated meeting, held March 9, Drs. C. F. Judson and J. C. Gittings exhibited a patient with a musical heart-murmur. Dr. J. Allison Scott presented a patient with grave anæmia and splenomegaly. There had been repeated attacks of what was believed to be malarial fever, and hyaline bodies had been found in the blood. On several examinations moderate leucocytosis also had been present. The condition had existed for eight years, and it was believed to represent malarial cachexia. Dr. T. L. Coley read a paper entitled "Pulmonary Abscess Producing Dextrocardia; a Case-report." The conditions were believed to be dependent upon rupture into the pleural cavity of an abscess of the lung, following pneumonia, and displacement of the heart to the right. The diagnosis was exceedingly obscure during life, and was cleared up only on post-mortem examination. Dr. D. L. Edsall presented a communication entitled "Concerning the Diagnosis of Liver Disease by Alimentary Levulosuria." It has been stated that in the presence of various disorders of the liver not susceptible of diagnosis in their incipiency by other means, the detection of levulose in the urine when this substance was administered by the mouth could be considered as conclusive. It was, however, impossible to confirm the accuracy of this statement in a small range of observations, levulosuria failing to develop in cases of undoubted liver disease, though appearing in one case in which there was no affection of the liver. Dr. D. J. Milton Miller reported a case of femoral thrombosis in croupous pneumonia. The condition is relatively rare, if one may judge from the small number of cases that have been put on record, and it almost invariably develops during convalescence.

Philadelphia Pediatric Society.—At a stated meeting held March 10, Dr. D. J. Milton Miller exhibited a patient with enlarged cervical and mediastinal Glands. Several operations had been performed, but recurrence followed each. Histologic examination of removed tissue disclosed on one occasion condition of hyperplasia, with the presence of giant-cells, but tubercle bacilli could not be demonstrated. On another occasion caseation was present. Faucial and lingual tonsils also were enlarged. The temperature was not elevated, but rather subnormal, and there was no constant increase in the number of leucocytes. The exact nature of the disorder was doubtful. Dr. George W. Norris exhibited a patient with multiple ossifying periostitis. The patient was an undersized boy of thirteen, who exhibited tuberous prominences on various bones, together with distortion and shortening, which had existed practically from birth, and for which there was no adequate explanation. Dr. L. H. Bernd reported a case of pericarditis and endocarditis. Dr. W. G. B. Harland read a paper entitled "Adenoids as a Cause of Enlarged Tonsils and Other Diseases." He dwelt especially upon the morbid significance of lymphoid hyperplasia in the nasopharynx, even when not of considerable degree, and of the advantage of its removal, whenever it gives rise to symptoms, and even in the absence of noteworthy symptoms, for the purpose of averting the undesirable consequences to which it may give rise. Dr. J. C. Gittings reported a case of œdema of the glottis. The complication occurred in a child suffering from scarlet fever, with enlargement of the cervical glands. Intubation was performed and various accessory measures were employed. The outlook appearing alarming, tracheotomy was advised but declined; nevertheless, the patient eventually recovered.

Pathological Society of Philadelphia.—At a stated meeting, held March 12, Dr. Herbert Fox read a "Report of a Series of Blood Cultures." The observations were made on fourteen cases of typhoid fever, blood being obtained from a vein at the flexure of the elbow, after sterilization of the tissues, by the introduction of a needle and aspiration with a syringe. The inoculations were made on liquid agar from which Petri dishes were cast, and the evolution of the colonies was studied. In many cases the staphylococcus epidermidis albus was found, in only one the typhoid bacillus, and in but one the colon bacillus. Drs. David Riesman and Justin Schwerin reported a case of ulcerative endocarditis with cerebral infarction. The patient had presented symptoms of endocarditis for ten months and was seized with right hemiplegia with aphasia. Autopsy showed the lesions of verrucose and ulcerative endocarditis, with an aneurysmal diverticulum on the anterior mitral leaflet, an aneurysmal dilatation of the aorta, embolism of the left lenticulo-striate artery and softening in the internal capsule. An old white infarct was found also in the spleen. Dr. Aller G. Ellis exhibited a heart showing serofibrinous pericarditis. The specimen was remarkable for the uniformity with which the heart was covered by the inflammatory deposit. Dr. Ellis exhibited also a heart with chronic tuberculosis of the pericardium and involvement of the myocardium. The pericardial cavity was wholly obliterated and the agglutinated layers of pericardium were enormously thickened. Dr. W. M. Late Coplin exhibited a glass specimen box with special clamp and device for labeling. One such box contained an enlarged lymphatic gland perforating the aorta. A second glass box contained "lung showing advanced gangrene in the upper lobe, beginning gangrene in the middle lobe, atelectasis of the lower lobe and bronchitis."

American Electrotherapeutic Association.—The thirteenth annual meeting of this association will be held at Atlantic City, N. J., on September 22, 23, and 24, 1903. The president of the association is Dr. Daniel Roberts Brower of Chicago; the Secretary is Dr. Clarence Edward Skinner of New Haven, Conn.

Typhoid Fever Epidemic in Philadelphia.—For the week ended March 14, 272 cases of typhoid fever

were reported to the Philadelphia Board of Health, with 38 deaths, as against 254 cases, with 21 deaths, for the preceding week, making a total of 2,984 cases reported since January 1, with 260 deaths.

Obituary Notes.—Dr. William P. Munn, former president of the Colorado State Medical Society and also recently the head of the Board of Health of Denver, died in Denver on March 13, during an attack of hæmoptysis. Dr. Munn was a graduate in medicine of the University of Michigan in the class of 1886. Prior to going to Denver in 1890, he lived at Pittsburg, Pa. He was genitourinary surgeon to the Arapahoe County Hospital, Denver.

Dr. T. Harper Rice died at Pottstown, Pa., on March 14. He was a graduate of the medical department of the University of Pennsylvania and a licentiate of the Royal College of Physicians, London, and of the Royal College of Surgeons, Edinburgh. He served as surgeon in the Boer army during the South-African war.

Dr. Marcus K. Goldsmith died at his residence, 1047 Lexington avenue, N. Y., January 14, 1903. He graduated in medicine from the University Medical College in 1885, and was a member of the Medical Society of the County of New York, the Harlem Medical Association, and the New York County Medical Association.

Dr. Charles H. Ohr died at his home in Cumberland, Md., on March 3, at the age of ninety-two years. He was a graduate of the University of Maryland School of Medicine in the class of 1834. He stood very high in the masonic order and was reputed the oldest Past Grand Master Mason in the world.

Dr. Alexander C. Peters died at his home in Newark, N. J., on March 8, at the age of sixty-three years. He was a thirty-third degree mason.

Dr. A. W. Church died in St. Francis's Hospital, Jersey City, on March 13, after an operation for appendicitis. He was thirty-three years of age. He was graduated from the Edinburgh University, and after his return to the United States he took some special courses at the College of Physicians and Surgeons in this city. He settled in Waretown, N. J., but retired from practice about two years ago.

Dr. Albertus Lyman Vandewater died in this city on March 2. He was born January 15, 1850, in Brooklyn, and was graduated from the Bellevue Hospital Medical College in 1870. He served for three and a half years at the old Centre Street Hospital, and was largely instrumental in the organization of the present ambulance service. He then acted as physician to the Tombs Prison for two years. He practised at Bay Shore for eight years, and then became medical inspector for the Equitable Life Assurance Society, subsequently being made assistant medical director of the company. This position he resigned in 1897 to become medical director of the Provident Savings Life Assurance Society, which position he held until his death. He was a mason in high standing.

Dr. Charles Archibald McCall died in Philadelphia on March 12, in his sixty-seventh year. He was graduated from the medical department of the University of Pennsylvania in the year 1855, and prior to the breaking out of the Civil War was for several years chief resident physician in the Pennsylvania Hospital. He entered the army as assistant surgeon and was later promoted to the rank of captain, being placed in charge of the Mount Pleasant Army Corps Hospital just outside of Washington, D. C., where he remained until the end of the war, being mustered out of the service in the year 1865 with the rank of major.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

KING EDWARD'S HOSPITAL FUND—SEPTIC SORE THROAT—ANÆSTHESIA IN THROAT CASES—DORCHESTER HOSPITAL—OBITUARY NOTES.

London, February 27, 1903.

The annual meeting of King Edward's Hospital Fund was held on Tuesday, the Prince of Wales presiding. The accounts were presented by Lord Rothschild and showed that £28,729 had been received from annual subscribers and £33,000 from donations. The capital had been increased by the munificent gifts of Lord Strathcona and Lord Mount Stephen, £400,000. The coronation gift amounted to £118,663, including Mr. Speyer's £25,000.

The Prince made a genial speech thanking all who had contributed to the success of his first year's presidency, and saying he was desired by the King to say His Majesty watches the growth of the fund with as much interest as ever. The Prince announced that it was decided to extend the operations to the limits of the County Council, and observed that 23 per cent. of the patients came from the provinces. He hoped, therefore, the cities and towns which had been so liberal in the coronation year would continue to help. He looked forward to the time when not only the hospitals but convalescent homes attached to them will participate more fully in the benefits of the fund.

For several years there has been a growing opinion among laryngologists that various forms of acute inflammatory diseases of the throat are not pathologically distinct. In 1895 this view was taken in a paper before the Medico-Chirurgical Society, and this month another paper before the same society enforces the view by the description of four cases with bacteriological report. Some laryngologists and some general physicians had previously held this opinion, and looked upon simple or mild cases and severe, erysipelatous, phlegmonous, and even gangrenous cases as differing rather in degree than in essential nature. The advent of bacteriology confirmed their views, and they are, therefore, ready to join their juniors in looking on all these cases as due to streptococcic infection. Clinically, all septic cases may be regarded as identical, but pathologically this cannot be so confidently asserted, since varieties of the streptococcus may be concerned. To return to the four cases related at the society. They were described by Mr. De Santi: One was a mild case, another was gangrenous, a third had also pericarditis. In all four the streptococcus pyogenes was found, and in three, injections of antistreptococcic serum were successfully employed, the other case being lost sight of. Not only this organism, but other pyogenic cocci are credited by many with the power of producing all forms of inflammation, the variety depending on the quantity and virulence of the organism introduced into the system and on the resisting powers of the system at the time. It will be admitted that Mr. De Santi's cases support this view, although it is evident that many of the milder cases have another origin—possibly also some of the severer. Mr. De Santi seemed to recognize this, for he warned his hearers of the danger of the serum treatment unless the streptococcus were found.

Dr. De Haviland Hall considered that a variety of organisms might produce similar conditions, as shown by the late Dr. Kanthack with regard to ulcerative endocarditis. He mentioned three cases in children which appeared, clinically, to be diphtheria, but on bacteriological examination turned out to be due to staphylococci.

Sir D. Duckworth had always held that streptococcus infection could give rise to all degrees of inflammation, from the slightest to the severest, and he advocated the use of mixed sera, as it was always uncertain what variety of streptococcus was being dealt with, and he had never seen any harm from such sera.

Mr. Waggett related a case of mild sore throat without a serious symptom, which in four days developed pus in front of the sternomastoid. He evacuated the pus and recommended immediate incision in all such cases, as they probably depended on the virulence of the organism.

Dr. Dundas Grant said local symptoms might be slight with constitutional severe. The aspect and voice might suggest peritonsillar abscess when no swelling could be detected. He related such a case with rapid death from laryngeal obstruction. He thought great relief was often obtained from the use of ice.

Dr. Poynton related some interesting experiments which tended to show that the number of organisms

and the resistance of the subject did not explain the results. The virulence of the organism seemed a more plausible solution, but that factor had been in some experiments reduced to zero, and he looked to a fourth factor, viz., a tendency inherent in microbes to produce special poisons. This had to be reckoned with in all investigations on the unity of the streptococcic group.

Sir F. Semon agreed with Mr. Waggett that the disease often attacked men in good health, but some had had sugar in the urine at the time or previously. He favored serum treatment, but as the disease might be due to any of the pyogenic groups the results might differ.

In reference to the foregoing discussion, I would remark that similar cases to those described are sometimes rapidly fatal, with or without signs of laryngeal œdema, to which death is often ascribed. On the post-mortem table this condition is sometimes found, but often in only so slight a degree as to be of doubtful significance, and quite as often it is not found at all. The possibility of œdema causing death is not to be denied, but there is the probability of cardiac failure being quite as often the cause, and that, too, without any definite abnormal appearance of the heart.

A case of death following the administration of nitrous oxide was lately reported which may have been one of this kind. Dr. Maughan gave the details to the Society of Anæsthetists, and other cases were thereupon mentioned. Dr. Maughan's patient was a young woman with tonsillitis, in whom the constitutional symptoms were out of all proportion to the physical appearances. The gas was given to the stage of loss of light reflex, the face piece was removed, and at that moment breathing stopped. She was placed on the floor with forceps on tongue and artificial respiration tried for a short time. No air entered, and laryngotracheotomy was performed when a full deep inspiration was taken, and the color returned to the lips and cheeks. But the corneal and conjunctival reflexes did not return, and though the respirations continued for twenty minutes at the rate of twelve, they then became shallower and irregular and failed altogether after a further ten minutes. The heart sounds could be heard up to the last. At the post-mortem nothing was revealed beyond "extensive angina Ludovici and some œdema of the glottis."

Dr. Low related a similar case in which he was using chloroform. On the lightest possible degree of anæsthesia the patient became so bad that the chloroform was stopped. Recovery occurred sufficiently for the patient to answer questions, but death took place a few moments later. If the patient had not spoken, the death would have been attributed to chloroform.

Dr. Tyrrell suggested what seems a fair explanation—heart failure primarily due to septic infection, but hastened by the anæsthetic. There is no doubt that these septic cases do affect the heart, and sometimes to the extent of arresting it. The use of an anæsthetic might, therefore, in such a condition precipitate a fatal issue.

On Monday Sir F. Treves formally opened a new operating theater to the hospital at Dorchester, his native town. He contrasted the operative work of twenty-five years ago with that of the present time. The great increase was due to Lord Lister, who had made it safe to do what could not then be undertaken—resulting in the saving of thousands of lives annually, and the rescue of more thousands from a state of hopeless illness. The horrors of the old time had passed and the operating theater had become a chamber of sleep and hope. He presented a surgical table of the latest pattern to the theater.

Dr. Peregrine died on the 18th ult. in his ninety-third year. He was M.D. of Edinburgh, a member of both the Royal colleges, and at one time an examiner of the Apothecaries' Society, in which he became the Senior Warden.

Dr. Alexander Prior, who died in December at the age of ninety-four years, was Senior Fellow of the College of Physicians and M.D. of Oxford. He was a great traveler, a litterateur and naturalist. He published a book on the names of British plants (1871); a work, in three volumes, on ancient Danish ballads (1860), and was the author of several minor books.

Mr. W. C. J. Miller died on the 11th inst. He was for twenty years Registrar of the General Medical Council, and for twice that time on the staff of an educational paper. He was a courteous, cultured man, and something of a naturalist. He was not a medical man, and when he was appointed Registrar some irritation was expressed that a member of the profession was not chosen. But that is a way that doctors have when they have a chance. Witness the case of the coroners. The medical coroners have gained their offices by the support of the profession. Then they appoint deputies, and not one of them has appointed a brother doctor!

LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

THE CHOLERA—THE PLAGUE—MANILA'S WATER SUPPLY—PRACTICE OF PHARMACY IN THE PHILIPPINES—REDUCTION IN THE HOSPITAL CORPS.

MANILA, February 1, 1903.

THE cholera situation in the northern islands of the Philippines is steadily improving, as was to be expected with the advancement of the dry season. Northern Luzon, with the exception of a few isolated foci, is practically free from cholera. Manila, for the month of January, has had but six cases, and but three cases since the middle of the month. It is probable that the cases which have lately occurred in the city are the result of new infections imported from time to time from outside points. In this fact of the practical impossibility of quarantining Manila against infection from the land side lies the probability of another outbreak under the more favorable meteorological conditions of the rainy season. The disease is still very severe in the province of Albay, in southern Luzon, but is held in check or decreasing, as a result of the energetic efforts of the health authorities. In the Visayan group the epidemic is rapidly waning, apparently from natural causes. This tendency of the disease to sweep over a district with great violence, and then to die out, more from an apparent attenuation of virulence of the cholera bacillus than the lack of susceptible material, has been characteristic of the present epidemic. In the southern islands the disease prevails with great severity in the country districts, though rapidly decreasing in the larger towns. Among the Moros in Mindanao the disease has had a very high mortality, a fact which has no doubt materially influenced the military situation in the production of a cessation of hostilities. Several hostile chiefs have died of cholera, and their fighting men decimated and disorganized. A few cases have occurred among the troops in Mindanao, but the efforts of the army surgeons have kept it away from practically all soldiers who have obeyed the sanitary orders. As an instance of the severity of the disease among the villages of the Mohammedan Moros, the mortality of some of the small villages in Zamboanga Province, Mindanao, from the beginning to the end of the outbreak in those villages, is as follows:

NAME	POPULATION (ESTIMATED)	DEATHS REPORTED
Mariki	50	11
Balabac	150	31
Pangapuyan	50	11
Malanipa	500	120
Sininuc	25	18
Taluk Sungei	1,500	118
Booboo	30	9
Lanigan	30	10

The number of cases of cholera occurring in these towns is not known. Some of the smaller villages, where the common source of water supply seems to have become infected, have been fairly wiped out. One fact in the present epidemic is very apparent—the infection varies in virulence with the locality, and even under the worst conditions about 20 per cent. of the population seems to have a complete natural immunity to the disease.

Further south, in the Jolo and Tawi-Tawi groups of islands, the disease is very severe where it has gained a foothold, but tribal prejudices and lack of ready communication operates to restrict travel by the natives, and greatly assists in preventing the transportation of the cholera germ into new and uninfected localities. The sparse population and absence of large towns also prevents the spread of the disease. These facts are of much importance from a sanitary standpoint, for the Americans have as yet no sanitary, and scarcely any military, control over the Moros, and when the disease breaks out among them it is impossible to give them any assistance or to institute measures for its control.

The Moros are, if anything, even more dirty in their habits and customs than the northern Filipino, and when the cholera infection is brought into one of their insanitary villages, the mortality is very high. The Sultan of Jolo seems to be fully aware of the value of quarantine in keeping out the infection, and has surrounded his court with every restriction to prevent the disease from reaching his family and retainers. The military surgeon, with the troops at the town of Jolo, has been very successful in his efforts at protecting the soldiers of his command, and so far the disease has failed to gain entrance to the walled city of Jolo, though prevalent over the entire island up to the line of fortifications. This is a good example of how readily cholera could be prevented from spreading among

the natives if they could only be induced or forced to submit to the necessary restrictions.

Of course, with cholera epidemic in the American islands of Tawi-Tawi, it was to be expected that the disease would be carried over to the main island of Borneo, only about forty miles distant. This has been the case, and cholera is now raging among the Malays of British North Borneo, starting from the port of Sandakan, and is now gradually traveling southward over the islands. The British control is still loose, and there is no sanitary organization to combat the disease, which will certainly extend to Dutch South Borneo and Sumatra, it having already gained direct access to Java by another route, and is now very severe in the vicinity of Bandjermassin. The extension of cholera through the entire Malay Archipelago may be expected during the present year—it will certainly knock at the gates of Australia, and if it gains entrance, will follow the trade route to South Africa, East Africa, and Madagascar.

Efforts are at present being made by the medical authorities of the civil government and army to secure the coöperation of the Spanish and native priests in the task of controlling cholera. It is realized that but little can be done to stamp out cholera, except by the education of the natives to a proper knowledge of the nature of the disease, and the best methods for its prevention and control. The Filipinos are distrustful of all officials, and particularly American officials, and evade or ignore sanitary regulations as far as possible. They are, however, completely dominated by the priests, and if the latter can be brought to assist in a campaign of education, much good can undoubtedly be accomplished.

Another effort for the control of cholera is to be made through the teaching of elementary hygiene in the schools established and operated by the American Government. At present there is no simple textbook suited to the needs of these islands, but it is understood that one is in process of preparation under the auspices of the insular sanitary authorities. Circulars relative to the prevention of cholera, published in the several languages used in the archipelago, are also to be widely distributed in the hope of robbing the visitation of the disease, during the coming rainy season, of many of its terrors. This education of the rising generation will not have as much effect upon the present epidemic as in elevating the future sanitary standards of the natives.

Plague still continues in Manila, though the cases are few in number. One occurred recently in the Walled City, which has so far practically escaped the disease. The disease is almost invariably of the bubonic type, and practically all the cases are fatal. Although the infection seems to be largely limited to the districts largely occupied by Chinese, the latter do not seem as liable to contract the disease as the Filipinos in the same districts.

Plans are being prepared for increasing the water supply of Manila, which is insufficient for the needs of a growing population and increasing business interests. A preliminary survey is being made, and an excellent drainage basin in the vicinity of the village of Montalbon has been determined. At present the water supply is so deficient that during the day there is no flow in the pipes of the upper floors in the buildings of the Walled City, and the older portions of Manila. The present watershed of the Mariquina valley is also so thickly populated as to be a constant source of danger to the health of the city. A large part of the native population of Manila still draws its water supply from shallow wells and polluted surface waters.

The Commissioners for the Philippines have recently passed an act regulating the practice of pharmacy, under which candidates who have served as pharmacists' assistants for a period of four years, even though they are not graduates of colleges of pharmacy, are entitled to appear for examination before the board which has to do with the licensing of pharmacists to practise. Graduates of schools of pharmacy must serve as assistants for two years before taking these examinations. The action of the Commission was in opposition to the desires of the pharmacists, who urged that no one be licensed to practise pharmacy who had been graduated from a school of pharmacy.

A reduction in the number of the Army Hospital Corps men on duty in the Philippines has just been ordered, by reason of the abandonment of many stations in conformity with the present plan of concentration of troops. The hospital force is to be cut down to 5 per cent. of the total white troops, and 3 per cent. of the native scouts, thus reducing the strength from about 1,500 to 1,000 men. This reduction is to be effected by the discharge of all men not of excellent character and adapted to the service, the transfer of others to the United States, the cessation of all new enlistments, and of re-enlistments, except in the case of exceptionally desirable men.

OUR ALBANY LETTER.

(From Our Special Correspondent.)

The Senate Judiciary Committee listened for two hours one day last week to the pros and cons of the Registered Nurses Bill. All concerned in the hearing were agreed as to the following points: (1) There should be a standard established by law indicative of what constitutes a competent (registered) nurse. (2) No legislation should be enacted which would exclude from such a class, women who have up to now deservedly earned the distinction of being trained nurses—accordingly these, without prejudice, should be exempt from examination tests. (3) The law should exempt from its provisions those who, previous to its enactment shall, in good faith, have commenced the study of their calling at a registered school for nurses. (4) Every student of nursing, desirous of being licensed as a registered nurse, must have had a preliminary academic education. (5) The Regent's office should be the authoritative center for (*a*) passing on the academic and professional qualifications of all candidates for such title and for (*b*) appointing the examining board.

As stated, there was no dissension expressed on the above points, but there was a considerable difference of opinion as to what the character of the membership of the board should be. The Nurses' Association wants that all members of the board shall be nominated from and by their body and that the regents shall appoint the board from such nominees. Representatives from the State Society submitted that the board should consist of five nurses and three physicians, each of the latter, if thought desirable, to be a representative of one of the three forms of practice recognized by the State. Inasmuch as physicians are the teachers of nurses, and as the latter, in the main, are employed by and on the recommendation of physicians, and moreover, as they have the best opportunities of judging of their fitness for their work, it is but reasonable to not only concede but to urge medical representation in such a body. Women are untried and certainly unskilled in matters of this kind and will require executive assistance. Who better than the physician to aid them in such a contingency? A registered nurse's bill should certainly be passed; the Legislature should make it effective, *a priori*, in the manner suggested.

Senator Stewart's bill, amending the Public Health Law so as to give the Commissioner of Public Health added power to abate nuisances, to combat epidemics and to appoint local health officers, has had its first hearing. Opposition appeared in the person of a New York City physician, representing the anti-vaccinationists, against what he termed the "compulsury vaccination clause, only. "We are opposed to uncleanliness! We object to being infected with a disease and the concomitant dangers of the operation, in order that an exploded theory as to prevention and cure may be practised on us! When a soldier is drafted in his country's service and returns from the field, injured or damaged in health, the State pensions him. By a parity of reasoning the State should stand willing to indemnify the individual who, as an unwilling victim is made to stand as a buffer 'against alleged public calamity.'" Such was the gist of the opposition argument. The Health Commissioner in reply did not attempt to convince the Committee as to the worth of vaccination as a preventive to smallpox, excepting to state that scientists, the world over, were convinced of its efficacy, and to state that experience proved that those countries which practised vaccination most thoroughly, suffered least from death and disaster from smallpox. He contended, moreover, that the bill was not one calling for compulsory vaccination, excepting as it applied to a restricted household or locality in which smallpox appeared as a scourge. One excellent clause of the new bill provides for a four years' term for local health officers and added compensation for any extra-hazardous service they render. The bill is designed ultimately to free such appointments from political control, and is in this particular a primary step in the direction of the Medical Record's recommendation for the creation of the post-graduate degree of Doctor of Public Health.

The rally in support of educational unification under Regent's control is daily gaining strength. The part which the medical profession has, and is taking, is highly creditable. They are standing shoulder to shoulder with educators in all academic and professional branches and, unless pressure of a nature not yet in evidence is brought to bear, the Stevens Bill will become a law and education and politics in New York State will forever be divorced. When that time comes the Empire State will be the educational clearing-house of the world.

The Buffalo Health Commissioner and his deputy have consented to serve as representatives of the State depart-

ment of health during the prevalence of the typhoid fever epidemic now raging in West Seneca, Erie County. At the present time there are 170 cases of well-developed typhoid fever, largely among the foreigners employed in the local steel company, and there is danger that the Buffalo water supply may become contaminated.

There seems to be danger lurking to the citizens of New York State in the proposition, now before the New Jersey Legislature, to construct an immense trunk sewer which is to take the sewage from a large section of the State of New Jersey and discharge it into the waters of New York State. The New York State Health Commissioner urges that a consultation of the authorities of the two States be held previous to the adoption of any such proposed procedure, so that proper arrangements may be made to safeguard the citizens of Saten Island and vicinity from possible dangerous consequences.

The Ways and Means Committee of the Assembly has under consideration a bill introduced by Mr. Graeff appropriating a total of $115,000 "for the treatment of incipient pulmonary tuberculosis" at the Ray Brook, New York, State Hospital. This bill, if passed, merely provides for the construction and furnishing of the proposed buildings. A subsequent appropriation will be necessary to run the plant. It is to be hoped there will be no delay in consummating the State's previously announced policy of attacking tuberculosis at Ray Brook in the manner familiar to your readers and in keeping with the suggestions of prominent members of the profession, learned in this subject.

The McCabe pure ice bill was recently considered by the Senate Public Health Committee. It would prohibit the cutting of ice, for domestic purposes, in the Hudson River between Waterford (above Troy) and Coxsackie. It is averred that eighty sewers empty into the Hudson between these points. The ice dealers are opposed to this bill and have secured an adjournment in order that they may be heard in opposition.

The Elsberg bill for the abolition of coroners and the substitution of "medical examiners" in their place, is being steadily advanced. It is claimed that a political understanding has been arranged which may succeed in passing the bill, notwithstanding the fierce opposition which is being waged by the friends of the present law.

If Assemblyman G. H. Smith's bill becomes a law, epidemic proclamations need not be posted in second-class cities. We would suggest to the various legislative committees of medical societies that they inquire as to the whys and the wherefores of this proposed departure.

A bill has been introduced by Assemblyman Hughes providing for the acquisition of a site for a State hospital for the insane in the northeastern part of the State. If, as claimed, present accommodations for the insane are inadequate, the State should not be remiss in providing them.

Governor Odell has signed a bill, thus making it a law, which provides that not less than six nor more than eleven surgeons, actively connected with the Brooklyn Eye and Ear Hospital, shall be members of its board of directors.

The bill to provide for the licensing of barbers has been advanced in the Assembly to the order of third reading.

A bill has been introduced in the Assembly making it a misdemeanor to carelessly distribute drugs and medicines.

MEDICAL SUPERVISION OF UNIVERSITIES.

To the Editor of the Medical Record:

Sir: Much interest has been deservedly taken in the recent outbreak of typhoid fever among the students at Cornell, and this disease, arising as it does from unhygienic conditions, and the resultant deaths would seem to point to the conservation of health and the saving of human life as a very necessary adjunct to the college and university administration.

These educational centers are made up of the best blood in the land, coming in from all over the country and destined to exert a strong influence in our future history, and upon the health of the student everything touching his future success may depend. The responsibility of the college is greater even than that of the home—in that it aims to more intelligently direct the abilities of those entrusted to its care—and we cannot but feel that the health of the students should be as much a matter of deep solicitude by the college authorities as any other one thing connected with the college life. To allow a large body of students to be free from a close medical supervision is not only unwise, but it is unjust to all concerned, parents, students, and friends.

No excuse made by college authorities should be allowed to stand against the appointment of a thoroughly competent and consequently experienced medical man, to whom all cases of illness of every kind and description should be reported at once and properly cared for.

C. Spencer Kinney.

February 25, 1903.

Progress of Medical Science.

The Boston Medical and Surgical Journal, March 12, 1903.

A Case of Habitual Dislocation of the Shoulder-joint.—J. Collins Warren reports the case of a man who has dislocated his shoulder-joint about fourteen times in four years. The operation recommended by Burrell and Lovett was performed; an incision four inches long was made from the coracoid process downward and outward along the inner border of the cephalic vein. The tendon of the pectoralis major was exposed and divided on the greater portion of its extent. The head of the humerus was rotated outward, and the insertion of the subscapularis was brought into view. By dropping the head of the bone backward this muscle was relaxed and its lower edge could be differentiated from the capsule. By freeing the lower edge of this muscle the capsule was exposed, and a piece of it, an inch long by three-quarters wide, excised and the wound closed with silk sutures, putting the capsule on the stretch. The wound healed by first intention. Two years later the patient reported that he had had no further dislocation of the shoulder.

Report of a Series of Cases of Movable Kidney.—H. D. Chadwick has in the past three years had the care of twenty-eight patients suffering from symptoms referable to a movable kidney. Many of them had been going about from one physician to another, finding no relief, and being considered for the most part as hypochondriacs or neurasthenics. The proper treatment of the affection seems to the author to depend upon the severity of the symptoms rather than upon the amount of inability. When the abnormal inability becomes a menace to a person's health or limits his usefulness, fixation is the only treatment that will give relief or produce a cure. An operation was performed on fifteen of this series of cases, and the results have been satisfactory, with the exception of one case. This was one of the earlier cases, and after a few months the kidney again became movable. The author supposes that he did not split the capsule enough for adhesions to form, and when the stitches gave way the former conditions returned. Appendicitis is frequently found in persons with a misplaced kidney, due probably to the chronic congestion caused by the displaced organ.

Limitations of the Uhlenhuth Test for the Differentiation of Human Blood.—A. E. Austin has found by experimentation that this test is not as fully applicable as has been represented, and that it can be employed only under the most limited conditions; that other fluids of the human body, like effusions and exudates, are of little value, and that the fluid from placentas can be used only when it is perfectly fresh, and that much longer time and more repeated injections are necessary than he had been led to suppose from the first over-sanguine reports of the earlier investigators. From one experiment he learned that pleuritic and hydrocele fluids produce but slight, if any, specific action upon the rabbit, unless a certain amount of blood is mixed with such fluid. In another experiment, a supposedly immunized rabbit serum to human blood gave precipitates with both human and rabbit blood-stains. Moreover, the serum which contains the active principle cannot be preserved on slips of filter paper, and an active serum which has been kept for a long time in the refrigerator has also lost the greater part of its efficiency, and acts very weakly, if at all, upon human blood-stains.

New York Medical Journal, March 14, 1903.

Some of the Complications of Abdominal Surgery.—R. T. Morris mentions anæsthesia, danger of iodoform poisoning, and hemorrhage as contributing possible complications in the work of the abdominal surgeon. With chloroform we may have vasomotor paralysis; with ether, disturbances of the gastric mucosa (through which ether is rapidly eliminated during and after anæsthesia), respiratory tract, and kidneys. We may give the patient small quantities of hot water after operation, or if vomiting is severe, we may wash the stomach out. The bronchial mucosa may be irritated by the refrigerating influence of the ether and its direct irritation on inhalation or by the process of excretion. In the kidneys a preëxisting nephritis is exacerbated or primary disease may be set up by prolonged use of ether. Curiously enough, some cases of nephritis caused by excretion of toxins from an acute infective process in the abdominal cavity will cease instantly in many cases after ether anæsthesia, provided

that the focus of infection has been rendered inactive by the operation. Iodoform poisoning may be confounded with septicæmia, but in the former the wound does well but the patient does not; in the latter, both do badly. In the former, free iodine is found in the urine. In hemorrhage occurring after abdominal operations the prognosis is not so grave if the blood remains within the peritoneal cavity as it is when blood escapes externally, provided the retained blood does not become septic. The reason for this is because the blood in the peritoneal cavity is still in circulation in a way, owing to the action of the lymphatics of the peritoneum, which take up the fluid portions rapidly and return them to the blood vessels, even though after making the round they again escape into the peritoneal cavity.

The Diagnosis and Treatment of Hereditary Syphilis.—The clinical histories of eleven cases are given by E. Harrison Griffin, who believes that many cases treated as tuberculous are really syphilitics. Hutchinson's teeth are present in only 10 to 15 per cent. of hereditary syphilis. A certain number of so-called hereditary cases in children are probably only simple tertiary cases in which the primary stage has been overlooked and allowed to run its course unchecked. When syphilis is introduced in a family, all the children born will show symptoms of the disease, and the severity of the symptoms will depend upon the amount of poison that is in the blood of the parents at the time the child is procreated. This statement is true unless the parent or parents have received proper treatment, and for such a lengthened period as to combat these symptoms. In every doubtful case coming under observation the buccal cavity should be most carefully inspected. It is a cavity the inspection of which throws more light on an average diagnosis than any other cavity of the body. In regard to the removal of dead bone from the roof of the mouth, the author's experience leads him to believe that it is better to keep it in position, as it serves as a shelf on which new bone cells may form. In this way a new palate may form and perforation be avoided. The reason why these cases are so often overlooked is that this form of the disease is seldom dwelt on in college teaching. The student is taught that the syphilitic mother will miscarry and her skin will bear the copper-colored spots of her infection. Her child, if she comes to term, will inherit her disease, but here the story ceases at its most interesting point. Nothing is said as to how the child will inherit, in what shape it will be infected, or as to the nature of its inheritance. These symptoms are passed over and the student is left, like the lecture before him, to grope for the symptoms in the dark, untaught and uninformed. Thus the common practice of the past and the universal practice of to-day is, if a case is not understood, give the patient potassium iodide; it may be tertiary syphilis or possibly hereditary syphilis. This is not medicine, this is chance.

Medical News, March 14, 1903.

Surgical Treatment in Non-malignant Diseases of the Stomach; Results and Indications.—Henri Hartmann states that the mortality in the operations for non-malignant diseases of the stomach depends almost entirely upon the physician and the early diagnosis. Success, operative as well as therapeutic, will come only as some special indications are followed. Atonic dilatation is rarely an indication for surgical interference. In pyloric stenosis the operative treatment is indicated as soon as the diagnosis is made. The acute ulcer, without any complications, is cured by medical treatment, when this treatment is sufficiently severe. In chronic ulcer, surgical treatment is indicated only in the case of an ulcer with mechanical troubles, and in those of an ulcer which is situated on the pylorus and which gives the pyloric syndrome. Delay is of no avail. In cases of excessive hæmatemesis, the operative mortality is high, the cure by medical treatment frequent. But cases of small and repeated hæmatemesis require surgical treatment. Gastroenterostomy seems to be, in the non-malignant diseases of the stomach, the best operation.

The Etiology of Colds.—James J. Walsh declares that the word cold is probably the most used and the least understood in the practice of medicine. Usually the seat of the affection is the respiratory tract. Those who live in a dry, very cold climate are not so subject to colds as those who live in a moist, changeable climate. Changes of temperature are not the important etiological element. An ordinary cold represents a reaction of mucous membranes, sometimes of serous membranes, with a consequent increase of secretion. Cold is only the predisposing cause for the contraction of colds. Undoubtedly bacteria of various kinds enter largely into the problem. Sometimes the inspiration of irritating substances, vapors or fine dust, may give rise to a catarrhal condition that resembles a cold. Colds in the head are almost surely due to bacterial invasion. Not infrequently pharyngitis and tonsillitis will follow mouth-breathing of cold air. There are always in the mouth a number of more or less pathogenic bacteria, and when the resistance of the tissues is lowered, pathological effects follow. Such is especially liable to occur if the person has come out of an overheated room in which there were many people or much dust. It is in affections of the respiratory mucous membrane below the larynx that bacteria in the breathed air are most important. Usually an attack of bronchitis or pneumonia will be found to be preceded by a visit to some place in which there was a large crowd of people. Such assembly rooms should be so built as to be exposed to the action of sunlight. Delicate individuals should avoid such places, and the stronger ones in leaving such halls should delay for some time in the cooler air of the corridors. A very striking indication that a cold is due to microbic invasion is that the process is nearly always accompanied by fever, due to an absorption of toxin into the circulation which disturbs the heat-regulating mechanism. The efficient cause of a cold is commonly further off than the patient imagines.

Journal of the American Medical Association, Mar. 14, 1903.

Bacteriologic Examination of the Blood During Life in Scarlet Fever, with Special Reference to Streptococcemia.—From his observations and experiments, L. Hektoen concludes that so far as scarlatinal streptococcemia is concerned streptococci occasionally may be found in the blood of cases of scarlet fever that run a short, mild, and uncomplicated clinical course; that streptococci occur with relatively greater frequency in the more severe and protracted cases of scarlet fever in which there also may develop local complications and clinical signs of general infection, such as joint inflammations, but even in the grave cases of this kind spontaneous recovery may take place; and finally, that streptococcemia may not be demonstrable in fatal cases of scarlet fever. The theory that scarlet fever is a streptococcus disease does not seem to receive any direct support from this work. Full references are given to the literature of the subject.

Some Rare Forms of Chronic Peritonitis.—A. G. Nicholls considers this malady with special reference to its association with productive fibrosis and hyaline degeneration. He makes the following division of the cases according to the nature of the exudation. (1) Chronic exudative peritonitis, in which there is a considerable outpouring of serous, serofibrinous or fibrinopurulent fluid, with loose plastic adhesions; fibrous bands are few or absent. (2) Chronic exudative and adhesive peritonitis, presenting less exudation, but with somewhat numerous and firm adhesions, often leading to sacculation of the contents. (3) Chronic hyperplastic peritonitis, in which there is serofibrinous or fibrinopurulent exudation, but more or less generalized adhesions are the rule, together with the formation of firm nodules or continuous sheets of hyaline fibrous tissue. Illustrative clinical histories are given. The treatment of all forms is essentially surgical. Abdominal section sometimes benefits a simple hyperplastic, the same as it does a tuberculous peritonitis. Tapping is generally necessary at increasingly frequent intervals. Diuretics are of doubtful benefit. Caffeine is recommended as the best remedy.

The Philadelphia Medical Journal, March 14, 1903.

The Treatment of Tropical Dysentery with Sulphur.—T. H. Weisenburg gives some interesting notes: In the acute cases the patients were kept as quiet as possible, all medication was withdrawn, and a milk diet enforced; they drank sulphur water exclusively and were given a bath in the sulphur spring every morning. The chronic cases were allowed to take moderate exercise, were fed on milk, eggs, fish, beef and vegetables, took a bath twice daily, and drank sulphur water. The results were excellent. In a month the acute cases were cured, and the chronic cases in from three to six weeks.

Some Points on the Management of Infectious Diseases.—A. G. Young declares that pulmonary tuberculosis occupies the first rank in the list of infectious diseases which are dangerous to the public. The sanitary precautions to be observed by the patient are the disinfection of the sputum or, better, its destruction with fire. Paper spit-cups should receive the sputum and should be burned with their contents. Corrosive sublimate solution may be used as a disinfectant of infectious dust in rooms which have been occupied by consumptives. Efficient work in the control of diphtheria must go hand in hand with the work of the bacteriological laboratory. Persons infected with this disease should be isolated. Antitoxin should be used and disinfection should be thorough. The two most potent factors in the spread of scarlet fever are: mild cases which escape the attention of physicians, and the failure to maintain isolation until the very end

of desquamation, till the hands and feet are entirely smooth. The correct diagnosis of mild and atypical cases of typhoid fever is of prime importance in the prevention of the spread of this disease. The main prophylactics are cleanliness and disinfection. The possibility of the infection being carried by flies must be remembered. When called to a suspicious case of smallpox, the physician should take ample time to make a diagnosis. Until this can be done, every suspicious case should be promptly isolated. Suspects should never be put into rooms with cases of smallpox. All exposed persons should be vaccinated at once. The necessary precautionary measures in pneumonia relate to the care of the sputum, and are the same as have been given for pulmonary tuberculosis. These measures are also advisable in grippe. As to whooping-cough and measles, all infectious pupils and all persons from houses in which there are cases of whooping-cough or measles should be rigorously excluded from the schools.

American Medicine, March 14, 1903.

Artificial Respiration in Carbolic-acid Poisoning.—Walter S. Cornell reports a case in which the quantity of acid taken was between two fluid drachms and two fluid ounces. The stomach-tube was inserted and the stomach thoroughly washed out with two quarts of water, containing eight ounces of epsom salts and four ounces of sodium bicarbonate. A hypodermic of ($\frac{1}{40}$ gr.) strychnia and ($\frac{1}{80}$ gr.) atropine was given. The heart-beat was not palpable and there was no radial pulse. A running, soft carotid pulse of 110 could just be felt. There was absence of respiratory movement. Whiskey was given hypodermically and by rectum. Artificial respiration was instituted, and at the end of thirty minutes the patient made a single, weak inspiratory effort. A little later he was breathing feebly but regularly.

On Transplantation of Tumors.—Leo Loeb believes that no organism sensitive to cold can be the cause of tumor formation. He concludes that after transplantation of these tumors there does not exist any appreciable period of latency in the growth of the peripheral transplanted tumor cells. They begin to multiply almost at once. Serial sections show that apparently separate tumor nodules of sarcoma may be connected by rows of cells. Tumor nodules smaller than a pea, which never did expand actively when examined microscopically after two months, showed an active mitotic cell proliferation, which is in all probability neutralized by the corresponding destruction of cells. By cutting out a piece of such nodules an active growth may be produced. Sarcomatous cells are phagocytic and may take up extravasated red blood-corpuscles. It is not improbable that transplantation of sarcoma will be shown to be more frequently successful than that of carcinoma, although transplantations of different varieties of carcinoma have been successful. The fact that not infected, fresh pieces of sarcoma can be successfully transplanted into the majority of animals of the same species proves that a predisposition for the growth of tumor cells is not the main factor which prevents or favors the formation of metastases. Transplantation of tumor cells, through so many generations, would seem to prove that the life or ordinary tissue cells may, under conditions not realized in one organism, be able to live much longer than the individual to which they belong.

The Lancet, February 28, 1902.

The Gelatin Treatment of Hæmoptysis.—H. M. Tickell mentions the objections to the hypodermic use of this remedy—pain, necrosis of tissue, rise of temperature, and possible tetanus. In place of this method he extols rectal injections, the solution being prepared in the following manner: 50 gms. (about $1\frac{3}{4}$ oz.) of gelatin are dissolved in $1\frac{1}{4}$ liters (2 pints $3\frac{3}{4}$ oz.) of boiling water and boiled very gently for one hour when the volume is reduced by evaporation to one liter. The solution is then cooled down to the body temperature and a quarter of a liter (nearly 9 oz.) is slowly passed into the rectum from an ordinary irrigator. The injection is given three times a day until the sputum ceases to show any trace of blood. Only a few cases have been treated in this manner, but the results are promising. The simplicity of the method places it within the reach of every practitioner. It is painless, free from danger of infecting the patient, and causes no rise of temperature. It seems to have an efficacy equal to that of the hypodermatic method without any of the latter's dangers.

The Treatment of Epileptics.—F. Beach believes in the "home treatment" of epilepsy. The patient should lead a quiet life, free from excitement, and should be subjected to cold baths or cold sponging daily. Out-door exercise and a moderate degree of mental work are necessary, and care should be taken to place the patient in such circumstances as will promote his welfare and recovery. It is necessary that he should be careful, prudent, and temperate in all things. Children who are the offspring of a neurotic family require to be brought up carefully, and later should be put into some occupation in which they will be free from excitement and worry, in which the work is light and the hours of employment are not long. As to drugs, he gives the bromides in large doses, favoring the combination of ammonium, sodium, and potassium. If for any reason but one salt is used, the ammonium salt is to be preferred. It may be combined with antipyrin, and the combination seems especially useful in lessening the number of attacks when a bromide dose alone has failed to effect this result. During this time iron tonics and cod liver oil should be employed for the maintenance of nutrition, and occasionally it is well to give a high rectal saline enema. The colony system of housing epileptics is highly commended.

A New Method of Treating Fractures of the Shaft of the Femur.—J. P. Lockhart Mummery thus describes his method of treatment: An extension stirrup is applied with strapping from the ankle to the knee in the usual way and the stirrup is fixed round the footpiece of a Macintyre's splint, the thigh-piece of which should be made long enough to reach well up to the fold of the buttock. On the under side of the thigh-piece and close to its upper margin a metal hook is fixed. The best splint for the purpose is a Macintyre, made so that the length of the thigh-piece can be adjusted by means of a thumb-screw and with a flat metal hook attached to the under side. An anterior splint for the thigh is then made of Gooch's splinting, or, better, of gutta-percha, padded with a double layer of lint, and fixed to the thigh with webbings passed around the Macintyre splint. The fracture having been set, the splint is now adjusted with the knee bent nearly to a right angle, and the limb is fixed with bandages or webbings, as the case may be. A leather strap, which should be about an inch in breadth, is now passed through the lugs on the carriage of a Salter's cradle, then round the thigh-piece of the splint and caught in the hook on the under side. The buckle is then brought to one side and the strap is tightened until the buttock and the thigh on that side are lifted off the bed; when the strap is sufficiently tight it ought to be possible to pass the open hand beneath the buttock on the injured side. Another strap is then passed round the lower end of the splint and fixed to the cradle to support the leg; this strap must not be too tight or it will depress the upper end of the splint. The upper strap will need tightening from time to time to make up for stretching, etc. All that is necessary in order to examine the site of fracture is to remove the anterior thigh splint. By this method very powerful extension can be easily secured, and with very little attention will remain efficient. The weight of the thigh and buttock tending to slide off the splint draws the upper fragment away from the lower; the latter is prevented from moving by the extension strapping and stirrup round the foot-piece and by the bent position of the limb. The chief advantages of this method are: (1) The nursing is very easy, as there are no weights, etc., and the cradle is the only thing that rests on the bed. (2) There is less tendency to movement at the site of fracture than with most other methods, as if the patient moves his body or it should become necessary to move him for the purposes of nursing, the distal portion of the limb and the splint will tend to move with him rather than for the movement to take place at the site of fracture. (3) The splint is comfortable and the limb is in the natural resting position of semi-flexion. (4) The apparatus is simple and easily applied. Movement of the knee-joint can be carried out from time to time by screwing the splint straight with the key while the thigh is supported by an assistant; this can be done without undoing the splint at all.

British Medical Journal, February 28, 1903.

Recovery from Tuberculous Meningitis.—A. Humphrey Davy had under his care a child of eight years with this affection. He put her on a course of creosote-vasogen, 20 per cent., commencing with five to seven drops in milk, gradually increasing to twelve drops. After ten days' *x*-treatment the symptoms began to abate. The treatment was continued for four months. After six weeks' change of air the child returned to school and has been well ever since.

Case of Eclampsia Fatal after Delivery.—C. Nelson Thomas was called to a patient in labor. She was unconscious and had had three convulsions during the hour before. A healthy child at full term was born, and the placenta immediately expelled. The patient regained consciousness and took a dose of ergot and bromide. About eighteen hours later the convulsions returned. The pupils were minutely contracted, and would not react to

light; the breathing was stertorous, with much frothy expectoration; the pulse was 130, temperature 104° F. The bowels had been well opened and the urine was loaded with albumin. There was no apparent œdema. The writer injected ½ gr. pilocarpine hydrochlorate with ½ gr. morphine acetate. The patient was quieter and sweated profusely, but in an hour had another convulsion. Then ½ drachm of chloral hydrate, with ½ drachm of potassium bromide, was injected into the rectum. In another hour the pilocarpine and morphine injection was repeated. She grew worse, however, and died in a few hours.

Case of Dilatation of the Pylorus for Simple Stricture.—Horatio P. Symonds describes the symptoms of a man of forty years who suffered from dilatation of the stomach. His illness had extended over a period of eleven years. No abdominal tumor could be felt, but the stomach was was found, by percussion, to be very much distended. There had been no vomiting of blood. Malignant disease was excluded, and the diagnosis made of simple stricture of the pylorus. The patient was anxious for an operation, and for a week previous he was kept on a bland diet, and received 8 gr. of benzonaphthol every four hours. At operation the abdomen was opened through the rectus muscle below the xyphoid cartilage. The stomach was much distended. The pylorus was steadied with the left hand, and with the index and middle fingers of the right a part of the anterior wall of the stomach was invaginated through the pyloric orifice, and dilatation of the latter was carefully accomplished by separating the fingers. The anterior wall of the stomach was then drawn out through the abdominal wound, and a longitudinal tuck was run in it by a continuous suture of the applied peritoneal coats. This tuck included that part of the stomach which had been used in the invagination manipulation. The wound was then closed. He remained in the hospital a month on careful diet, and then went home. In five months he went to work, and has had no stomach symptoms since. He says that he feels like another man.

The Presence of Diphtheria Bacilli in Atrophic Rhinitis.—J. Odery Symes presents the results of his investigations on this subject. The type of "diphtheria-like" bacillus that he describes is peculiar to the condition—atrophic rhinitis. The constant occurrence of this bacillus is by no means conclusive evidence that it plays any part in directly exciting the disease. But it is found in atrophic rhinitis only, and in this respect is unlike the bacillus mucosus, which has been demonstrated in cases of rhinitis sicca and syphilitic disease. Reports of this bacillus state that the morphological and cultural characteristics are those of the diphtheria bacillus, and that the organisms were pathogenic to guinea-pigs, producing the same lesions as the Klebs-Loeffler bacillus. If the identity of this bacillus with the Klebs-Loeffler bacillus can be established, then atrophic rhinitis may be regarded as a chronic form of nasal diphtheria. The following facts also support this theory: (1) In diphtheria the accessory sinuses of the nose are constantly infected. Bacilli may remain in the sinuses for prolonged periods, exciting a purulent, seropurulent, or serous discharge. (2) Chronic suppuration in the accessory sinuses is, in the opinion of many eminent rhinologists, the direct exciting cause of the conditions of ozæna and atrophic rhinitis. (3) Multiple cases of atrophic rhinitis in the same household occur from time to time, as one would expect if the process were a true infection. (4) An attack of diphtheria may be the starting point of atrophic rhinitis. (5) Atrophic rhinitis, like diphtheria, attacks females more than males; it is a disease of early life, and induces a pronounced anæmia and leucocytosis. (6) Atrophic rhinitis has been successfully treated by diphtheria antitoxin. (7) In atrophic rhinitis the type of diphtheria bacillus does not alter during the progress of the case, a fact which has recently been found to hold true in acute faucial or nasal diphtheria.

Deutsche medicinische Wochenschrift, February 19, 1903.

Subconjunctival Injections.—Karl Wessely by a series of experiments upon rabbits, seeks to explain the mode of action of subconjunctival injections of solutions of sublimate and sodium chloride as such are effectively used in various diseases of the eye. Others have thought that the efficiency of the injections is to be ascribed to the local increased acceleration of the lymph currents or leucocytosis produced thereby, or in the case of bactericides, such as sublimate, to the antiseptic actions of these substances. Careful experimentation has shown that none of these factors is responsible for the action of the injections, since the presence of such processes cannot be demonstrated in the tissues of the eye following the injections. The chief change that can be demonstrated as the result of such injections relates to the composition of the aqueous humor. This becomes very much richer than normal in albuminoids. This increase in albuminoids is due to the irritating action of the injected substances upon the blood vessels, ciliary body, and its immediate neighborhood. This produces a congestion of these blood vessels, and therefore an increased transudation of albuminoid substances from them into the aqueous humor. It is well known that the protective substances of the blood are always to be found in combination with the albuminoids of the same, and it would hence be rational to assume that coincident with the increase of serum albumin in the aqueous humor, various protective substances (hæmolysins agglutinins, etc.) would appear in the same, or if previously present would be increased in amount. Experimentation shows that this is the case. If a rabbit's blood, in the usual way, is made hæmolytic against ox blood, the aqueous humor of such a rabbit possesses no hæmolytic properties. If now in addition subconjunctival injections of sublimate or sodium chloride be made into one eye, it will be found shortly thereafter that the aqueous humor of this eye is markedly hæmolytic, while that of the non-injected eye still remains without hæmolytic properties. The same principle applies to the agglutinins. No experiments have as yet been conducted with the bacteriolysins, but it is probable that the like holds true for these substances. The action of these injections is hence to be sought in their local irritating properties which favor the production of a localized immunity. They should, therefore, be especially useful in the treatment of acute inflammatory diseases of the eye.

Münchener medicinische Wochenschrift, February 24, 1903.

Hemianæsthesia Alterans.—v. Rad reports a rare case in which the regions involved were the right side of the face and the left side of the body. The patient was a male thirty-seven years of age and the symptoms developed suddenly after a night of excessive eating and drinking. At the beginning there was marked vertigo and much difficulty in walking, the patient constantly falling toward the left side. The anæsthesic symptoms lasted for about six months, when they entirely disappeared, the health of the patient being fully restored. The diagnosis of the condition was made by careful exclusion, and of its cerebral origin there can scarce be a doubt.

Tuberculosis of the Larynx and Pregnancy.—Löhnberg says that tuberculosis of the larynx is especially apt to develop in pregnant women who previous to pregnancy possessed tuberculous lesions in other locations or a susceptibility to infection with the tuberculous bacillus. Five cases are reported, in two of which the patient was not tuberculous before conception took place. All of the cases were allowed to go to term. In all, the mother died of tuberculosis within a few weeks or months after the labor. Two of the five children lived and were apparently healthy. So far as can be judged from these cases the continuancy of pregnancy in tuberculous women or those predisposed to this disease is attended with great material risk, and the only safety lies in an early evacuation of the uterus.

Prognosis of Atrophic Cirrhosis of the Liver.—H. Ehret reports a case which shows that the prognosis of this disease is not necessarily fatal, as is generally supposed. Several authors have previously reported cases of apparent cirrhosis of the liver which terminated in recovery, but in none of these cases was the chain of observations complete, so that a certain amount of doubt is to be attached to their validity. In order to demonstrate the fact that it is possible for atrophic cirrhosis of the liver to terminate in recovery, a case must be presented which shows the following consecutive facts: (1) A fully developed clinical picture of this disease. (2) A complete disappearance of all the symptoms. (3) A continued absence of such symptoms for a period of at least twenty years, and until the death of the patient from some other cause. (4) The demonstration of the presence of the lesions of atrophic cirrhosis of the liver at the autopsy. In the case here reported all of these facts can be established. It is thus absolutely demonstrated that it is possible for this disease to terminate in recovery. In order that such may be the case, it is evident that two conditions must be present: (1) A sufficient amount of liver tissue must be left intact, so that metabolic processes necessary to the life of the individual may continue in force. Experimental observations have shown that a small number of liver cells are capable of a relatively large amount of work, and that thus a small amount of sound liver tissue can effectively compensate for much liver tissue that is permanently destroyed so far as its functional activity is concerned. Furthermore, the formation of *new* liver tissue where portions of this organ have been removed, has been conclusively proven. It cannot, therefore, be denied that in cases of cirrhosis an amount of sound liver tissue necessary to the life of the individual may be indefinitely preserved. (2) The interference with the circulation of the portal system must be overcome, so that œdema and the consequent

symptoms which threaten life may permanently disappear. That this may be accomplished by anastomosis with the blood vessels of the peritoneum and mesentery has been shown by a number of experimenters and the observations of Castaigne.

Berliner klinische Wochenschrift, February 23, 1903.

Albumin Nutrition.—M. Kaufman and L. Mohr report experimental observations with respect to the final disposition of the retained nitrogen in the body under forced nutrition. Krug believes that he has shown that under these conditions it is not possible materially to increase the amount of retained nitrogen and that forced albumin nutrition in men is extremely difficult. He hence thinks that the retained nitrogen is to be found as reserve albumin in the body cells similarly as reserve glycogen is known to be present. Lüthje comes to opposite conclusions, and thinks that the retained nitrogen is present in the form of albumins as they enter into the composition of active living protoplasm. The present observations tend to confirm Lüthje's views. It was found possible to markedly increase the amount of retained nitrogen by the forced feeding of individuals who possessed no organic disease, but whose general nutrition was markedly reduced. The final disposition of this nitrogen is, however, not a matter to be easily decided. Some light may be thrown thereupon by an estimation of the amount of the retention of the various salts necessary to the formation of protoplasm. This has been borne in mind in the present studies, and it has been shown that such retention is markedly increased. The final disposition, however, of these salts is not clear, since besides forming protoplasm they also enter into the formation of bone. Further observations are in progress concerning the disposition of these salts, and it is thought that in this manner the final disposition of the retained nitrogen may be ascertained.

Importance of the Reaction after Cold Baths.—Simon Baruch emphasizes the importance of a satisfactory reaction after the employment of cold baths in both acute and chronic diseases. The shock produced by the cold water is, if of proper duration, an important if not the chief factor in the stimulation of the circulatory and nervous systems, nevertheless it is the reaction which prevents this stimulation from being overproduced and the vital functions depressed, often dangerously thereby. In the treatment of acute diseases, such as typhoid fever, by cold baths the reaction becomes of double importance, for here depression from shock is exceedingly dangerous and often fatal. Here, especially, the endeavors to produce the reaction should be instituted *during* the application of the cold water. These measures are thermic, mechanical, and chemical. During the bath the patient should be briskly rubbed, so that the circulation of the superficial capillaries is actively stimulated. In this manner the *entire* circulation is accelerated, and not only are serious consequences avoided, but the congestion of the internal organs quickly relieved. Experience has shown that the addition to the water of certain salts greatly favors the production of the reaction. Those most suitable are the Nauheimer salts in the form of Sandow's tablets. If these principles and methods are followed, the use of cold baths in typhoid fever becomes a pleasure to both the patient and the physician, and the fear of the depressing effects of shock, entertained by many, vanishes. In chronic diseases the production of the reaction should immediately follow the application of the cold water and should be most energetically carried out. In employing cold baths the temperature of the same should be carefully regulated to meet individual cases, remembering that in fever patients moderately cold water produces a much greater shock than in those who are non-febrile.

French and Italian Journals.

Aneurysm of the Aorta Opening into the Lung.—Leclerc describes a patient who suffered from a barking cough as when the bronchi are compressed, and from crises of suffocation, in one of which he died. Radiographs which were taken demonstrated the existence of an opacity independent of the heart and ascending aorta, and which was slightly pulsatile. The diagnosis was made and was verified by autopsy. Both of the sympathetics were united and compressed by the tumor.—*Lyon Médical*, February 22, 1903.

Family Hæmoglobinuria in Malaria.—M. Luzzato reports the case of a father and two daughters who all suffered from malarial hæmoglobinuria, the disease proving fatal in two of the cases. The administration of quinine did not appear to be the cause of the condition, and, indeed, in one case the repeated administration of the remedy caused a disappearence of the symptom. The author concludes that in malarial districts there is an individual, congenital and familial predisposition to hæmoglobinuria, which becomes evident either when there is an invasion of parasites or sometimes after the administration of quinine.—*La Riforma Medica*, February 11, 1903

Diffuse Hypertrophy of the Maxillæ.—Adenot has a patient with this rare deformity. The child is ten years old and recalls slightly patients with tumors of the nasal fossæ and those of the adenoid type. Three years ago this child was operated upon for adenoids, but that trouble is evidently not the cause of the enormous deformity of the superior maxilla, the bones of the nose, and the inferior maxilla. The hands and feet are normal and there is no acromegaly. The thorax is somewhat rachitic. The family history is negative. The child is very intelligent. It is simply a case of diffuse hypertrophy of the maxillæ.—*Lyon Médical*, February 8, 1903.

A Rare Form of Masked Fever.—Vincenzo Piazza Martini concludes from his observations that nephritic colic, due to malaria, or fever masked under nephritic colic, has a definite clinical form. It occurs at regular intervals, sometimes even daily, now in the right and now in the left kidney, in persons who have had malaria. The pain may be accompanied by the malarial splenic tumor, and may coincide with the emission of uric acid crystals, which is a mere coincidence. The pain differs from that of nephritic colic due to calculus in that it is not accompanied by vesical disturbances; it disappears with quinine treatment and does not recur after the prolonged administration of arsenical preparations.—*Gazzetta Siciliana di Medicina e Chirurgia*, December 1, 1903.

Dilatation of a Deep Vein of the Forearm.—Tavernier reports this case. The operation was very simple: After incision of the skin, mass of fat, and fascia, the tumor was seen, and easily dissected. The venous trunk was cut between two ligatures. A third vein, which branched from the deep surface of the tumor to penetrate into the deep tissues, was likewise tied and cut. The tumor was in close relation with a nerve filament which bifurcated at the lower part of the incision and which appeared to be a branch of the musculocutaneous. It was perhaps to the compression of this nerve that the sufferings of the patient were due. The radial artery was not uncovered. The examination of the tumor showed it to be rounded, of the size of a small nut—a veritable venous aneurysm developed from the lower surface of the vein. The layer of fat which covered the tumor satisfactorily explained the absence of the blue coloration of the skin.—*Lyon Médical*, February 15, 1903.

Surgical Treatment of Purulent Ethmoiditis.—J. Guisez declares that the treatment of purulent ethmoiditis ought to be only surgical, and like that of every purulent collection from any intraosseous abscess. To open, curette, and drain at the most sloping point are the indications to be fulfilled. The opening can be made through the nasal fossæ, or through the orbit. The ethmoid cells may be approached more or less easily after the opening of the neighboring sinuses—by the frontal or the maxillary sinus. Surgical intervention is indicated in every case of purulent ethmoiditis. It ought to have two objects in view: By a generous drainage it should avoid the phenomena of retention which are the principal factor of encephalic or orbital complications, and it ought to aim at the radical cure of the purulent ethmoiditis. The after care and following intranasal treatment are of great importance. This should be persisted in as long as there is the slightest intranasal leakage, that is, for several weeks or even months.—*La Presse Médicale*, February 14, 1903.

Sepsis of the Respiratory Apparatus in Early Childhood.—Enrico Mensi states that septic infection occurs more frequently in the child than in the adult, because phagocytosis is less active, the alkalinity of the blood less marked, cellular reactions less energetic, the cells not being completely differentiated, and the bactericidal power of the fluids being slight. The local condition favoring the entrance and development of the infective germs are the active desquamative process in skin and mucous membrane, and the incomplete development of the stratum corneum of the skin. The mucous membrane of the respiratory tract is less protected than the skin; slight physical or chemical traumatism, elimination of the products of autointoxication, simple catarrhs due to infective general diseases and local nervous disturbances, modify its vitality, its circulation and secretions, diminish the epithelial and lymphatic resistance, and the bactericidal power, so that it is unable to oppose the growth of the microorganisms causing rhinitis, stomatitis, laryngitis, bronchitis, broncho-pulmonitis, pulmonitis. Aseptic precautions at birth and hygienic measures later, including an abundance of air and sunlight, with absolute cleanliness, constitute the best prophylaxis.—*La Riforma Medica*, January 7, 1903.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, Held March 11, 1903.

DR. WILLIAM HALLOCK PARK, IN THE CHAIR.

A Few Animal Parasites Sometimes Found in Man.—Dr. HARLOW BROOKS read this paper. He said that his observations had extended over a period of two years and had been entirely limited to the parasites inhabiting wild animals in captivity. He felt justified in stating that, as a rule, parasites were infrequent in wild animals in the open, but were commonly found in those in captivity, particularly when they pass through the generally filthy and certainly infected quarters of the average animal dealer. These animals frequently receive their infection from the exhibition paddocks and cages, generally because of the lack of knowledge on the part of the animal man of the importance of cleanliness and disinfection. It was a general idea among medical men that man became infected with parasitic diseases from handling these animals. He believed this was doubtless true in some cases, but he was convinced that it was not so common as popularly believed, for a large number of parasites found in the lower animals, although they belong to the same class as those found in man, were quite incapable of infecting man, the genus found in man differing in small but very important ways. This point was best illustrated in the *hook-worms*, many species of which have been described; the textbooks lead us to infer that the disease may be transmitted from one animal to another or to man. As a matter of fact this animal differs in nearly every variety of animal which it inhabits and for the greater part the worms infecting one family are quite unable to live in other animals and sometimes in different members of the same family. One variety of the ankylostoma duodenale was found infecting the intestine of dogs and a quite distinct species were found among foxes. One variety was found among sheep, another among cattle, and another had been found infecting and causing the death of a great number of the Alaskan seal pups. It had been shown that a variety of the uncinaria infecting men could not infect the dog family and the converse was probably true. The exact zoological status of the hook-worm was still in question and was further complicated by the fact, as stated by Stiles, that the disease as found in man was known by some fourteen different names, among the most common of which were ankylostomiasis, Egyptian chlorosis, tunnel-worker's disease and perhaps most correctly uncinariasis.

The Lesions.—The lesions produced by all species of hook-worm he said were practically the same in all animals and consisted briefly in the lodgment of the parasites in the duodenum, where they attack the mucous membrane (the worm being a blood-sucker); as the result of the lesions of the mucosa and as a result of the blood actually abstracted, serious and often fatal anæmia resulted. Stiles stated that this was further accentuated by a limitation of the absorbtive and digestive power of the gut because of the lesions of its mucosa. Some authors have claimed furthermore that a poison was formed which increased blood destruction.

Its Distribution.—The disease had long been recognized in Europe and the tropical countries, but had seldom been reported in America. As shown by Stiles, the disease had been endemic in the States bordering on the gulf of Mexico and certain of the Southern States. Capps of Chicago, in the *Journal of the American Medical Association*, collected fifty-one cases reported in American literature, two being from New York State. In nearly all instances they had been imported from the tropics, from Europe, or from the Southern States. Soldiers and civilians returning from Porto Rico, Cuba, and the Philippines are bringing the infection home with them. The disease was generally spread among earth-workers. Therefore, he believed that we would find the disease quite common in New York within a few years, because of the extensive tunnelling now going on and soon to be commenced by the Pennsylvania railway system. The gravity of the condition required a wide dissemination of the knowledge of the dangers necessary.

Varieties Found in Man.—He said there were two varieties found in man. One was known as the Old World hook-worm, found especially in the warmer parts of Europe, and the other was known as the New World species, first described by Stiles, and called the uncinaria Americana; this was found in Porto Rico, in the Southern States, and in the West Indies. In Cuba both species were to be found. Panama was infected by the Old World species. Therefore, both species were a menace to New York. The two varieties differed in the arrangement of their buccal spines, in the situation of the vagina in the female, and in the arrangement of the bursa copulatrix of the male.

Balantidium Coli.—Another parasite found in both man and animals was the balantidium coli. During the past year he found this to be the cause of a fatal form of ulcerative dysentery which carried off the entire orang family at the New York Zoological Park. The lesions were limited to the colon and consisted in the formation of ulcers similar in their microscopical appearances to those of amœbic colitis. The character of the lesions and the course of the disease as observed in apes corresponded very closely to that described by Malmsden as occurring in his original cases in man. In his cases he said there was no possibility of doubt but that they were the cause of the dysentery and that they produced the lesions found. There had been considerable doubt expressed on this subject in regard to the infection in the human. These doubtful statements were generally expressed in textbooks which had taken their conclusions from the statements of Malmsden in his original article. He believed that he had shown these conclusions to be erroneous, and he was pleased to find that the more recent writers were of a like mind. Strong who observed cases of tropical dysentery in the Philippines came to the same conclusion. The parasite found by him in cases of tropical dysentery was identical with that found in his cases. He had discovered it in the fæces of the Giant turtles from the Galapagos Islands, and it was from these that the orangs received their infection. Leukar found it in the pig in Germany, and Stiles found it in the American hog. Russell found the balantidium coli as well as the balantidium minutum in the fæces of dysentery among the soldiers in Porto Rico, but he was not able to satisfy himself as to its pathogenicity. The infection was most frequent in man in Scandinavia, where it is communicated to man by the pig, and most of the literature from there show that the writers are unanimous in pronouncing the infusorium a distinctly pathological agent. He said that nearly all the more recent observations of actual cases of infection tended to corroborate his conclusions. The importance of this parasite lay in the fact that it is being introduced into this country by soldiers returning from foreign service and suffering from tropical types of dysentery. So far as present observations went, this parasite was apparently transmitted from the lower animals to man, in whom it was probably more pathogenic than in any of the lower animals, excepting the higher members of the primates.

Misserchen Schleuche. This was commonly called "Rainey's corpuscle." At one of the meetings last year Dr. Brooks and Dr. Miller had reported the case of an elk which had died from the result of the presence of the Misserchen schleuche in the heart muscle. It was then stated that the parasite was rarely found in the human, although it was common in certain of the domestic animals used for food, particularly in sheep. The most prominent authority on meat inspection, Ostertag of Vienna, recommended that flesh containing this parasite

be not excluded from use as human food, presumably basing his conclusions on the rarity of the disease in man and on the fact that Pfeiffer and others had been unable to infect animals experimentally by feeding them with infected flesh. He said that these experiments had now been overthrown by those of Theobald Smith of Boston, who had been able to infect mice by feeding them the muscle in which the parasite was found.

He said that very little was known regarding the life history of this sarcosporidion. There could be no doubt that it was transmitted from animal to animal, probably through intestinal infection. The elk herd at the Zoological Park recently had become infected with the parasite; eventually it will cause the death of these animals for the reason that, following the observations made by Darwin, diseases of an infectious nature were particularly apt to be virulent in species unaccustomed to, but susceptible to, the new infection. In the elk, caribou, and native deer the infection invaded the heart muscle in most cases, rarely setting up a true myocarditis but a parenchymatous degeneration of the heart muscle, which was sometimes accompanied by fatty degeneration and infiltration. He felt convinced from the character of the disease, as seen at the Park, that it was transmitted from animal to animal, probably from infected soil on which the grass they ate grew or through the water which was supplied them. He said he wished to again state his thorough conviction that, although the parasite was rare in the human, still he believed that it could be transmitted through the ingestion of infected meat, and he thought that such infected meat should be thoroughly cooked when used for food. Cases had been reported by Kartulis, Barbaran and St. Remey, Rosenberg and Lindermann, while Leukar, on the other hand, stated that it had never been found in the human. The parasite belonged to a very large class, and since its life history was unknown, he thought we should accept somewhat carefully the statements that the forms found so rarely in the human are certainly those found frequently in the lower animals.

Dr. J. C. Roper referred to two cases of ankylostoma. Both patients entered the hospital for the relief of a marked anæmia. In neither case was there any diarrhœa. Blood examination showed from 25 to 30 per cent. eosinophilia.

Dr. L. B. Goldhorn said that the fæces should be set aside for several days and the ova would undergo segmentation. It was not easy to recognize the parasite itself, but the ova were quite characteristic and easy of recognition.

Dr. Harlow Brooks said that the ova sometimes became highly developed in the oviduct of the female before their discharge. Segmentation was rather common in the oviduct.

A Case of Filaria Bancrofti.—Dr. F. Tilden Brown presented some photographs which were taken by Dr. Sondern showing the filaria on the slides. The patient had been to Porto Rico for two years and entered Bellevue Hospital for the relief of pain in his left testis. He was a German, thirty-four years old. Examination showed the left side of the scrotum larger than the right; the testis was somewhat enlarged, but it was a question whether the enlargement was in the body or in the epididymis. About the center of the body and epididymis there was a hard and tender nodule. There was some fluid in the tunica vaginalis. A diagnosis of tuberculous epididymitis was made and operation advised and consented to. He enucleated the testicle, removed the epididymis and lower portion of the cord and a considerable amount of the vas. The nodule was found to correspond to the mediastinum. Cutting into this nodule revealed a cheesy-looking mass in the center. A smear was made with the expectation of finding tubercle bacilli, but, instead, unusual forms were discovered. These were in clusters and seemed to be the embryos of the filaria Bancrofti. The slides showed embryos in different stages of development. The eggs were of different sizes. An examination of the patient's blood at various times, during both day and night, did not reveal further embryos.

A Modification of the Chromatin Stain for Malaria.—Dr. F. C. Wood demonstrated a modification of the Romanowsky stain for malaria parasites. The specimen was hardened in alcohol. Then stained for ten seconds in a ten-per-cent. aqueous-solution of eosin. Then it was washed in water and a few drops of methylene azure applied. He had excellent and quick results from this method. An advantage of this method was that slides that are very old can be stained as readily as fresh ones. If there should be an excess of the stain it can be washed out with alcohol.

Demonstration of Blood Smears in a Case of Pseudo-Leukæmia Infantum.—Dr. L. B. Goldhorn said that he was asked to examine the blood of a child with an enlarged spleen, and the smears showed it to be a case of pseudoleukæmia infantum. The slides were well worth looking at. They showed very interesting changes in the red blood-corpuscles, as well as a peculiar condition of the leucocytes. Anæmia of a high grade was present. The red cell count was 1,800,000 to the centimeter. The red cells looked like normoblasts minus the nucleus and degenerated. Mytosis was present. Eosinoplilia was present. Myelocytes were also present but scanty. Mononuclear leucocytes were noted. The anæmia resembled the pernicious form very closely and also the pseudoleukæmia.

Dr. Eben Foskett said that the case had been under the care of Dr. Joseph Messenger for several months receiving tonic treatment and intestinal antiseptics. Dr. Messenger being ill, he saw the case for him two weeks ago when the child was suffering from an acute bronchitis. The abdomen was markedly distended and the liver enlarged. The spleen extended to within one inch of the umbilicus and as low as the iliac crest and was rather peculiar in having a sharp border. The child was twenty-eight months old. The anæmia still persisted, but not so much as three months ago. The mother had had eight or nine children and two died with symptoms very similar to those presented by this patient.

The Period of Development, the Time of Greatest Accumulation and the Persistence of Diphtheria Antitoxin in the Blood of a Series of 100 Horses.—Dr. James P. Atkinson, Assistant Chemist from the Research Laboratory of the Department of Health of the City of New York, read this paper. He said that the maximal capacity of horses to develop antitoxin varied greatly and depended to a certain extent upon the amount of toxin injected and the frequency of the injections. There seemed to be a maximal antitoxin limit for each horse beyond which it cannot be pushed. After reaching this limit, which was attained on an average four months after the toxin injections began, the blood serum might continue for a while, if the injections were continued, to contain antitoxin of the maximum amount, but sooner or later the quantity of antitoxin surely would diminish. The Health Department of the City of New York had from March, 1897, until May, 1902, made use of 100 horses for the production of antitoxin serum. In the majority of these horses the toxic effects of the first three or four toxin doses injected were more than neutralized with diphtheria antitoxin. The size of the first injections varied considerably. The earlier horse received 300 to 1,500 guinea-pig fatal doses of toxin with but little antitoxin, the later horse received 5,000 to 40,000 guinea-pig fatal doses of toxin fully neutralized. With each succeeding injection the antitoxin amount was gradually diminished. The toxin injections were increased each time by as much as was considered safe and repeated as soon as the temperature fell to normal, about every five or seven days. The doctor presented a table showing the relation of the series of toxin injections to the maximal antitoxin strength of the sera developed by the

horses. From the data that he gave from carefully selected horses of median grade he concluded as follows: (1) That about one-half will develop sera of 300 units strength per c.c. or greater, and that about one-fourth will develop sera of 500 units strength per c.c. or greater. (2) That the average development of maximum strength may be expected three to five months after the first toxin injections, according to the rapidity with which the toxin is pushed. (3) That horses capable of producing a high-grade antitoxin serve a longer period of usefulness than horses capable of producing medium-grade antitoxin.

Dr. William H. Park said that Ehrlich's idea regarding the development of the antitoxin was that the cells became accustomed to the overproduction and so reproduced One can readily obtain in from three days to three weeks an enormous accumulation of antitoxin. If these cells are pushed further they cease to produce as much antitoxin, for the cells have become overworked and cannot keep up the work. According to Ehrlich and other observers, after the injections are stopped the cells go on producing; but, according to his results, after seven or eight days there has always been a drop. This was against the opinion of Ehrlich and others and had nothing to do with the theory of production.

Notes on Systemic Staphylococcus Infection.—Dr. Emanuel Libman read this paper on staphylococcus aureus infection. He wished to prove that the staphylococcus aureus could be cultivated from the blood during life, and that the work could be done in such a manner that the question of the organism found being a contamination from the skin could be excluded.

The staphylococcus albus he believed did not occur in blood except as an ante-mortum invader. He was inclined to disregard the staphylococcus albus findings until he found a case in which such a finding was corroborated by the occurrence of the same organism in a metastatic focus. It was necessary to take special precautions in identifying a staphylococcus as being of the albus or aureus variety.

After a short description of the technique, Dr. Libman gave a brief report of twenty-three cases in which he had found the staphylococcus aureus in the blood. In every case the same organism had been isolated from the primary focus, if one was found, or if cultures had been made. The same organism had always been found in the metastatic foci, and often in the urine, and in the organs of the cases coming to autopsy. In 325 of the cases he had never obtained a colony of the staphylococcus aureus. So that when he did find this organism in the blood he was forced to believe from his experience that he could safely report the case as one of staphylococcus systemic infection to the clinician or surgeon. He drew attention to metastatic skin abscesses occurring in osteomyelitis. They occurred particularly in the scalp, but could be found all over the body. They were small and seemed to have their origin in the sweat glands. They always showed the staphylococcus aureus pure. He believed they represented lesions due to an attempt at excretion of the cocci by the skin. He did not believe this lesion had been described. At least it seemed not to be generally known.

The reports on the blood cultures had usually been made within twenty-four hours. In a very few cases, three or four days elapsed before a definite diagnosis was established. Of the twenty-three cases described five had recovered. The number of cocci found in the blood was not necessarily of diagnostic import. The amounts of blood used varied from one to fifteen cubic centimeters. In some cases several cultures had been made. He said that a detailed account of the cases would appear in the Transactions of the New York Pathological Society, March, 1903.

EASTERN MEDICAL SOCIETY.

Stated Meeting, Held March 13, 1903.

Louis J. Ladinski, M.D., President.

Typhoid Fever.—The special order for the evening was a symposium on typhoid fever.

Etiology and Prophylaxis.—Dr. Herman Schwarz read this paper. He said that up to the beginning of the nineteenth century typhoid fever was confused with typhus fever. In 1880 the bacillus of typhoid fever was discovered by Eberth. Modern bacteriology had shown that many of the organisms declared formerly to be typhoid germs were really not so, and hence had arisen the term para-typhoid. The germs of typhoid were found principally in the fæces, but in quite a large proportion of cases they were not isolated from the urine. In rare instances, when the lungs were involved, the bacilli were present in the sputa. The dead body seemed to inhibit the growth of the organism, but Petri and others had succeeded in obtaining the live bacilli as long as three months after the death of the person, a fact of much importance in connection with prophylaxis. Kitasato and others had shown that the strength of hydrochloric acid present in the stomach exercised but slight inhibitory influence on the typhoid bacillus. Water and milk were the common media through which the bacilli gained entrance to the human body. The vitality of the typhoid bacillus would be destroyed by whiskey in five minutes, and in half an hour by a mixture of equal parts of whiskey and water. Typhoid fever was most common between the ages of fifteen and thirty years. Chronic disease of the stomach, especially dilatation, predisposed to infection. Congenital immunity was probably more rare in this than in any other disease.

With regard to prophylaxis, there could be no question about one's ability to control the disease in cities by proper attention to the purity of the water supply. For the disinfection of typhoid stools freshly prepared milk of lime was useful; it should be sprayed on the bottom of the bed-pan. According to some authorities, the best disinfectant was a 1-to-1,000 solution of bichloride of mercury, used in the proportion of one-fifth of the bulk of the fæces. With regard to the inoculation treatment, statistics were quoted showing that of 244 persons so treated the mortality was 11 per cent., and of 157 not inoculated, the mortality was 16 per cent., a difference so slight that it did not admit of any deductions.

Symptomatology.—Dr. D. Robinsohn discussed this subject. He said that he had recently observed forty-nine cases of typhoid fever in hospital, and twelve in private practice. The temperature range was so very important in this disease that it deserved the closest attention. In bad cases the rise of temperature was abrupt, instead of gradual. In mild cases there was often only a gradual rise, followed immediately by a slow decline. In a few cases the temperature assumed the character of an intermittent fever. The course of the temperature might be influenced by many occurrences. When there was a profuse intestinal hemorrhage the temperature frequently fell several degrees. In a pregnant woman suffering from typhoid fever, the occurrence of abortion or of premature labor also gave rise to a very marked fall in the temperature. The appearance of complications, such as pneumonia and peritonitis, was usually associated with a marked rise of temperature, and later the temperature was apt to become very irregular. In bad cases it was possible for the typhoid fever to run its entire course without any elevation of temperature. The facial aspect was worthy of attention. In the initial stage the cheeks were flushed and the eyes bright; later on the patient had a dull and heavy look, and never presented that striking pallor so frequently observed in malaria. Sometimes the typhoid eruption was so profuse as to cover not only the body, but the extremities. The rash was present in forty-six of his cases. In the first week there might be little or no

change in the blood, but later on the quantity of hæmoglobin was greatly reduced. The number of colorless corpuscles was subnormal. The absence of leucocytosis was very important, and might be of diagnostic value in distinguishing typhoid fever from certain acute inflammatory conditions. The large mononuclear and transitional forms were increased, and the polynuclear cells were diminished. In threatening perforation of the intestine the leucocytosis was often very marked. The pulse was increased in rapidity, but not always in proportion to the elevation of temperature, becoming rapid and small with the exhaustion of the later stages. During convalescence the pulse gradually returned to the normal, and sometimes became abnormally slow. The spleen was enlarged and soft, thus distinguishing it from the hard spleen of malaria. The initial headache was of diagnostic significance. It was usually superseded in the second week by a dull pain in the head, and in the third week this was apt to give place to a low, muttering delirium. Early in the disease the tongue was moist and furred. In the severe cases the tongue became very dry, partly because such patients breathed with the mouth open. Intestinal hemorrhage occurred in about 3 per cent. With its occurrence there was evidence of sudden exhaustion or even of collapse. The most important symptom of perforation was sudden and severe pain, for the most part in the hypogastric region to the right of the median line. As a rule, there was muscular rigidity in this region which interfered seriously with palpation. Leucocytosis was very often present. If peritonitis supervened there were increased pallor and perspiration, a rise of temperature and an increase in the pulse, the latter becoming thready. Peritonitis might be present without perforation of the bowel, due to an extension from a typhoid ulcer. Cholelithiasis was very common after typhoid fever.

Diagnosis.—Dr. Louis Hauswirth presented this paper. He said that the type of the disease varied considerably in different localities, and age had such an influence that formerly it was considered that very young and very old persons were exempt from typhoid fever. The affections due to paratyphoid or paracolon organisms were chiefly of academic interest. In children the disease was mild and usually of short duration. The stools were frequently not characteristic, and the spots were apt to be few. Any continuous feverish condition in a child, especially occurring during the typhoid season, should lead one to think of typhoid. Bronchitis was apt to be an annoying feature. Typhoid affecting the kidneys occurred occasionally. In pneumo-typhoid fever it was occasionally of service to examine for the typhoid bacillus. In the ambulatory type of typhoid, symptoms simulating appendicitis, perforation or hemorrhage of the bowel might be the first warning of sufficient importance to cause the patient to seek medical advice. It was evident, therefore, that in order to make the diagnosis it was absolutely necessary to have a complete history of the illness. A preceding typhoid fever was generally, though not always, sufficient ground for the exclusion of typhoid fever. In doubtful cases no part of the body should be overlooked in the physical examination. The position in bed, the color of the eyes and the expression of the countenance were likely to give important information. The occurrence of a diffuse bronchitis in a person acutely ill was a sign of some serious acute disease, most commonly typhoid fever. Abdominal percussion was not so serviceable as palpation in typhoid fever. The spleen should be examined with the patient lying on the right side. The skin of the entire body should be closely examined for an eruption. The occasional occurrence of the Widal reaction in the blood of jaundiced persons should be remembered. The dilution employed for this test should be at least one in twenty, there should be an unquestionable cessation of movement and an agglutination of the bacilli. In doubtful cases the value of this test was inestimable, although in many of the frank cases of this disease the ordinary clinical phenomena were usually sufficient for the diagnosis. It most important to make frequent examination of the blood for the Widal reaction. The typhoid bacilli were often not found in the fæces before the end of the second week. A diminution of the white blood count was strong corroborative evidence of typhoid fever. The complications might give rise to a hyperleucocytosis. Cultures taken from the large veins often showed the presence of the typhoid bacillus quite early in the disease. Puncture of the spleen was a dangerous procedure that could not be recommended. The only eruption closely simulating the typhoid eruption was that appearing in persons perspiring freely, or who were enveloped in in wet packs, but in the latter the lesions were more of a bluish color. Mixed infections, as of typhoid and malaria, altered the "step-ladder" type of the fever. Fever cases accompanied at the height of the fever by profuse sweating were usually not enteric fever. The spleen was almost invariably enlarged and very early, and this enlargement lasted up to the time of convalescence. Relapses were almost always accompanied by a second enlargement of this organ. The pulse of adult typhoid patients was soft, irregular, and often dicrotic. The stools were usually of the pea-soup variety, but constipation was not infrequently present. Tympanites was so frequently present that like gurgling in the right iliac fossa it was only of corroborative diagnostic value. Pain and tenderness in the right iliac region were of importance in differentiating typhoid from appendicitis. Headache as a most significant symptom in the early stage. The diazo-reaction was of little value because it occurred so frequently in the diseases most apt to be mistaken for typhoid. The occurrence of herpes fairly early in the disease was fairly strong presumptive evidence against the diagnosis of typhoid. In "walking typhoids" complications were often the first symptoms pointing to the true nature of the disease. From typhus fever the diagnosis was especially difficult. The former usually began with a chill and high fever, and the cerebral symptoms usually developed rapidly. The temperature remained high, and was often associated with chills, while the rash was indefinite and involved the extremities as well as the trunk. The spleen was apt not to be appreciably enlarged. There were apt to be dyspnœa and cyanosis entirely out of proportion to the physical signs in the lungs. When a typhoid patient developed chills and a cardiac murmur, the diagnosis was often exceedingly difficult. Here blood counts and a search for the primary focus was all important. In meningitis the rigidity of the neck or back, the retracted abdomen, the cerebral vomiting, the slow pulse and irregular breathing pointed quite clearly to the diagnosis which might be confirmed by the results of lumbar puncture. Malaria required a blood examination, and sometimes the therapeutic test, in order to make the differential diagnosis.

Treatment.—Dr. Julius Halpern presented a paper on this subject. He said that during the last few decades the treatment of typhoid fever had been undergoing great changes. It was now a matter of ancient medical history that the mortality was reduced by Brand and his followers to 3.9 per cent. in a series of over five thousand cases. The present cold-water treatment was popular with the profession, not because of its control of one symptom, but because it was based on an effort to stimulate and support the nervous system and secure the elimination of the toxins. The baths not only reduced the temperature, but acted upon the nervous system in such a manner as to enable it to withstand the toxic influence of the infecting principle and the products of its evolution. This general reinforcement of the vital functions was shown by the increased tone of the heart's action and the improvement in the appetite and digestion, by the slowing of the respirations and by an inhibition of the nervous phenomena. The treatment was one which was directed against the disease in its entirety. In applying it, it was

very important to individualize it. In his opinion, the frequency, temperature, and duration of the baths should be determined by the degree of the toxæmia. The testimony here and abroad with regard to the efficacy of cold bathing in typhoid was conclusive, and showed that the the mortality varied from 3 to 7 per cent. No complications, except hemorrhage and peritonitis and excessive exhaustion, should be considered as contraindications to its use. The cold pack was not so generally useful in typhoid fever. Cold sponging, being one of the easiest methods in private practice, was often employed, and was quite efficient if properly carried out. A useful innovation was what was known as the cold siphon. A siphon bottle containing carbonated water was gradually discharged over the body, particularly over the thoracic region. It produced a feeling of exhilaration similar to that experienced after a cold bath. One could not yet speak with certainty concerning the value of the serum treatment of typhoid, but recently 356 persons had been so treated in Paris with a mortality of 3.7 per cent., which was a very favorable showing when one recalled that the usual mortality in that city was 19.3 per cent. The whole series of coal-tar antipyretics were not only useless but decidedly dangerous in typhoid fever. They were pure antipyretics, very fugitive in their action; in addition, they were cardiac depressors and blood disintegrators, although occasionally small doses of phenacetin as a sedative were permissible. The different intestinal antiseptics were harmless, but were not indicated, because it was manifestly impossible for them to exert their action in the glands and in many other parts of the body. A few doses of calomel at the outset of the disease would be found very useful, but this drug should not be used after the second week. The typhoid patient should be given water freely, not less than eighty ounces in the twenty-four hours. Perhaps the most important element in the treatment was the proper regulation of the diet. Milk, plain or in the fermented form, was the standard food. The great tendency at the present time was to overfeed the patient. The stools should be inspected, and if undigested casein were found in them it was evidence that the patient was receiving too much milk or that the milk was too strong. Under such conditions it was desirable to temporarily substitute expressed beef juice or eggs. It was well to withhold solid animal food for seven days after the fall of the temperature to the normal. When the pulse became dicrotic and there was an absence of the first sound of the the heart, alcoholic stimulants were indicated, and should be given freely. In conditions of marked exhaustion it might be necessary to resort to the hypodermic use of camphorated oil.

Complications and Sequelæ.—Dr. Morris Manges took up this part of the subject, referring to some of the more interesting ones that he had personally encountered.

Grip.—Mention was first made of the relation of grip to typhoid fever. His attention had been first called to this six years ago in connection with an ordinary mild type of catarrhal influenza. The patient recovered from this, and after an interval of ten days a typical typhoid fever developed very abruptly. About three years later Potain declared that he had not infrequently noted the close relation of the two conditions, and that the abrupt onset of typhoid fever was favored by the antecedent attack of the grip. This contention was sustained by a number of medical authorities. There were at present in the Mount Sinai Hospital three cases exemplifying this relationship.

Paratyphoid.—At the same hospital there had recently been a series of cases giving the usual phenomena of typhoid fever, and only distinguished therefrom by the shorter course, the absence of the roseola, and the negative Widal reaction.

Diphtheria.—The throat should be examined as a routine measure in typhoid fever, for he had already reported six cases in which pharyngeal diphtheria complicated this disease.

Pneumonia.—Pneumonia had complicated typhoid fever much more frequently in recent years than formerly. The sputum in these cases was usually scanty, and the patients were too apathetic to cough. The sputum rarely presented the ordinary characters of pneumonic sputum, and personally he had never been able to cultivate the typhoid bacillus therefrom. Pneumonia was often overlooked in typhoid fever. It should be remembered that in the aged typhoid fever might easily present the usual clinical picture of pneumonia.

Impaction of Fæces.—Impaction of fæces caused trouble more frequently than was generally supposed. The free use of milk, the apathetic condition of the patient and the long course of the disease all favored impaction of fæces, and tended to accentuate the constipation which was so common in typhoid fever. His attention had first been directed to this by a persistence of the fever without any obvious cause in a patient who was having daily stools. Finally, a high-oil enema was given and retained for several hours, with the result that there was a stool of enormous size, and the temperature promptly and permanently fell.

Starvation.—Mention was made of a case in which starvation had given rise to mental symptoms, including wild delirium.

Tetany.—He had seen but one case of this exceedingly rare complication, which he attributed to the exceedingly severe grade of toxæmia. The case terminated fatally.

Mastitis.—He had seen mastitis as a complication in two cases, both of which recovered. The mastitis did not present any special features; suppuration did not occur, and attempts to cultivate the typhoid bacillus were unsuccessful.

Purpura.—Purpure had been met with in one very severe case which had been neglected before admission to the hospital. When first seen the patient was thoroughly septic, and he died in two or three days. This complication was of very grave prognostic significance.

Periostitis.—He had observed periostitis of the ribs in three cases associated with abscess. In all of the cases the abscess developed from the costal cartilage rather than from the rib itself.

Pyelitis; Cholelithiasis.—Pyelitis had been observed in three cases, and in quite a number cholelithiasis had complicated the typhoid fever. In the last four cases of cholelithiasis recovery took place.

Intestinal Perforation.—During the last year in the Mount Sinai Hospital there had been no less than eight cases of intestinal perforation, the largest single group of cases of this kind that he had met with in this hospital. The diagnosis had been correctly made in each of these cases. A chill occurred at the onset in five of the eight cases; abdominal pain was present in all; abdominal distention was present in only five. Dulness in the flanks was noted in only one case. The temperature yielded no reliable information. The leucocyte count was increased considerably in five cases, and very slightly increased in one, while there was no change at all in two cases. Seven of the cases were operated upon and all but one recovered; the one patient who was not operated upon, a boy of twelve years, also recovered. At times perforation of the bowel was exceedingly easy to diagnosticate, but in many other instances, especially those seen in private practice, it was almost impossible to make the correct diagnosis.

Manifestations in Children.—Dr. Henry Koplik presented this paper. It was now generally acknowledged, he said, that infection of typhoid fever could be conveyed from the mother to the fœtus, usually through the placenta. The child, if alive when born, usually died soon afterward with symptoms resembling those of sepsis of the newborn. The disease in the newly born ran an atypical course, the affection partaking of the nature of a hæmatogenous disease. The mortality was very high. Typhoid fever occurred up to the age of two years beyond any question. Some of the older reported cases, however,

could not be accepted because serum diagnosis was not then in vogue. Typhoid certainly did occur in children below the age of two years, though not so frequently as in later childhood. During the first year and most of the second year the infant was fed on food which had been subjected to more or less heat. Ambulatory and apparently mild cases of typhoid would infect others; hence it was easy for the younger children of a family to become infected; indeed, he had noted a remarkable susceptibility to infection among such young children. The mortality in those under two years of age could not be stated with accuracy, but it was probably larger than was generally appreciated. Griffith had collected a number of cases under the age of one year with a mortality of 50 per cent. In the second year of life the mortality was less. One could not speak understandingly of the mortality in adults without taking into account the occasional occurrence of a very severe type of the disease. The older the patient the greater the mortality. In the Mount Sinai Hospital from 1898 to 1901 the mortality from typhoid fever in adults was 9.2 per cent., and in children, 6.6 per cent. Holt had collected 2,600 cases in children under the care of twelve observers, and found the mortality to be 5.4 per cent., but a series of this kind, which ignored the ages of the patients, did not give a correct impression. In children under ten years of age the mortality varied between 6.6 and 10 per cent. In children, even a severe toxæmia did not prevent the case from running, to all outward appearances, a mild course. On the other hand, in the mild cases the severest complications might ensue. Intestinal perforation was not uncommon in children, and occurred for the most part at the beginning of the third week. In most instances it was preceded by hemorrhages. In his own experience there had been two cases of undoubted perforation in a series of about 100 typhoids, showing that the percentage exhibiting this complication depended upon the severity of the particular epidemic.

Treatment of Some Surgical Complications.—Dr. John F. Erdmann discussed this subject.

Abscess of the Liver.—Dr. Erdmann said that, according to Osler, solitary abscess of the liver was very rare. For subphrenic abscess the method of approach was by ordinary laparotomy, and if the patient were greatly exhausted the operation should be done under local anæsthesia. When the abscess was situated behind the ribs a subpleural and trans-pleural diaphragmatic operation was required. After exsection of some of the ribs and the dissection away of the pleura, puncture was made through the diaphragm. The general peritoneal cavity was excluded by gauze packing. This method was only useful in those cases in which the abscess occurred low in the costal region. In seven years at the Gouveneur Hospital there had been but one abscess of the liver complicating typhoid fever, and that one occurred in the fourth week of the disease. A second abscess was discovered later, and at the post-mortem examination multiple abscesses of the liver were found.

Perforation of the Gall-bladder.—The literature showed that there had been five complete operative cases of this kind with one death, and that of 27 cases not operated upon, all died. Personally, he preferred to make the incision through the rectus muscle. Suture of the perforation was not to be considered, if only because of the friable nature of the tissues. The operation to be employed should be complete removal of the gall-bladder, although in special cases the welfare of the patient might be best subserved by doing cholecystotomy.

Cholecystitis.—Cholecystitis was a common complication, and should be treated by cholecystotomy if the patient's condition were bad; in other cases, cholecystectomy was the operation of choice. If the latter operation were done no drainage would be required.

Intestinal Perforation.—According to the statistics given by Osler in 1901, perforation of the intestine occurred in 2.7 per cent. of the cases, and was most common between the third and fourth weeks. He thought the general mortality was between 25 and 32 per cent. The majority of the cases were operated upon under eight hours after perforation was suspected. Of those terminating fatally the average time was ten hours. He was inclined to believe that not more than three or four hours should be allowed to elapse for the subsidence of shock.

Dr. William H. Thomson opened the discussion with some observations drawn from his own experience, and bearing more especially upon the treatment of typhoid fever. He premised his remarks by saying that any deductions regarding the treatment of such a disease as typhoid fever should be based upon not only an extensive, but a prolonged experience with the disease.

His Own Statistics.—In 1869 he had published a paper, giving his experience with typhoid fever for ten years in the Roosevelt Hospital. At that time the mortality there, in his service, was found to be 3.5 per cent., and this mortality had been kept up since that time. In the last 112 consecutive cases under treatment, and occurring since last September, there were four deaths, or 3 per cent. It was not fair to judge of hospital mortality from mere figures, because so many cases were almost moribund at the time of admission. He had excluded all cases dying within four days after admission, in order to make his mortality of 3.5 per cent. If these were included, the mortality would rise to 6 per cent. Of ninety-three women in the first series there were six deaths, but all occurred within five days of admission. The first of the four fatal cases in the last series died on the day of admission. The second of these patients went through to the middle of the third week very well, and then developed certain abdominal symptoms, with which was associated a rise of the leucocyte count to 17,000. His surgical colleague was very sure that intestinal perforation had occurred, and insisted upon operating. This was done, but no perforation was found, and no peritonitis or cholecystitis. The patient rapidly improved for a few days, and then died suddenly from some unknown cause, as no autopsy was permitted. The third fatal case was that of a man who had gone through the typhoid fever up to the end of the fourth week very comfortably and without complications. Hemorrhage then occurred from the mouth, after that from the bowel, and from the kidneys and finally from various other parts of the body. The post-mortem examination showed hemorrhages throughout the intestinal tract and also of the genitourinary tract. This was not at all like the purpura of typhoid fever. The fourth fatal case was a clear example of death from typhoid fever. The patient was in the private division of the hospital, and had a severe type of the disease. Dr. Thomson said that in his service tympanites was very uncommon, yet this woman had a severe and persistent tympanites, and, moreover, from the beginning of the disease there was a tremor of the tongue. He disliked this last symptom, as it indicated to him very extensive intestinal ulceration. The patient died from perforation on the thirty-sixth day of her illness. Attention was called to the fact that in his wards he no longer saw the classical picture of typhoid fever as depicted by the older writers. This was unquestionably because of the different treatment employed. Out of 725 cases diarrhœa occurred after the first week in the hospital in only 8.7 per cent., and this he attributed very largely to the abandonment of the old beef-tea treatment. After the first week in hospital tympanites had occurred in only 11 per cent.; hemorrhage in 7.3 per cent., and in no case was the direct cause of death. In 87.5 per cent. of the cases there was no delirium at any time; in the remainder there was some delirium, but usually not severe. Pneumonia was present in 2.7 per cent. Bronchitis occurred as an initial symptom in 40 per cent. Peripheral neuritis was present in 7 per cent. Relapses were noted in 15 per cent. In cases left to nature, diarrhœa occurred in about 60 per cent. of the cases and tympanites in about 80 per cent.; hence the dimin-

ished percentages must be due to the treatment employed. Formerly delirium was thought to be a constant feature, yet in his cases it had occurred in only 12 per cent.

Treatment.—The diarrhœa he believed to be due to the inability of the stomach to digest. There was no other disease which reduced the pepsin and the peptic power of the stomach to the same extent as did typhoid fever, not even cancer of the stomach. He, therefore, gave ten grains of saccharated pepsin and twenty grains of the subcarbonate of bismuth every three hours, night and day, and occasionally also gave hydrochloric acid. This, apparently, accounted for the relative absence of tympanites. He regarded tympanites as a very serious complication, and its persistence as indicative of serious intestinal ulceration. For diet he used exclusively equal parts of milk and lime water from the beginning to the end of the disease. In the first week it was possible by proper management to greatly reduce the danger of subsequent toxæmia. At this time there was marked diminution in the excretion of urine, due to a condition of infection of the blood, which, if allowed to persist, would favor the rapid multiplication of the typhoid bacilli. To encourage renal secretion he gave five grains of calomel and thirty grains of the compound jalap powder every other night, and morning and evening a rectal irrigation of two or three gallons of normal saline solution at a temperature of 112° or 115° F., using for the purpose Kemp's irrigating tube. This treatment was kept up until the sixteenth or seventeenth day of the disease. Baths were given whenever the temperature passed 102.5° or 103° F. When it was found that the reaction from the cold bath was not favorable, he recommended the use of the warm bath. It would be found that frequently the warm bath gave better results, but one could not determine in advance which treatment would prove the more effective. He did not believe the warm bath produced its favorable effect by its influence on the temperature, but by its action in increasing the elimination of the toxins by the kidneys. For failure of the heart he used strychnine, but relied most upon camphor. He believed that nearly all of the cases giving a severe toxæmia were examples of mixed infection, most commonly an infection with the colon bacillus.

Typhoid Rare in Young Infants.—Dr. William P. Northrup said he was convinced of the relative insusceptibility of infants under two years to typhoid infection. He had seen only six children under that age in whom typhoid had occurred, and each case occurred in connection with an epidemic and after repeated exposure to severe infection. As a rule, the onset was insidious, and was associated with diarrhœa and continued fever, but without much prostration. The fever was mild and of a remittent type and short duration. His argument was, that when little children had typhoid fever they had it like adults, and when they did not have true typhoid fever, they had something else which resembled that disease and was often confounded with it. In all six of these cases of undoubted typhoid fever the diagnosis was easily made on the usual clinical symptoms and signs. He was skeptical regarding all cases of alleged typhoid fever in infants under two years of age not intimately associated with other cases. In adults typhoid fever was usually called something else; in children something else was usually called typhoid. Sporadic influenza could certainly simulate typhoid fever so closely that it was next to impossible to differentiate it from that disease except by the presence of certain positive signs and symptoms. Central pneumonia was sometimes confounded with typhoid fever, but this should not occur if one recalled what he liked to call "the O'Dwyer Rule," viz.: "When the respiration-pulse ratio departed from the normal ratio of one to four and approximate one to three, look out for trouble in the chest." Malaria could be excluded by the use of quinine and enterocolitis by treatment.

Dr. Willy Meyer said that it should be remembered that the typhoid bacillus belonged to the class of pus-forming bacilli. It had been observed that after repeated hypodermic injection of a typhoid patient in one part a subcutaneous abscess might develop, whereas other patients receiving these injections with the same fluid and in the same region of the body would not develop abscess. Bacteriological examination of the abscess in the typhoid patient would reveal the presence of the typhoid bacillus. Closed cavities, such as the pleura, were sometimes affected, giving rise, for instance, to empyema. If on aspiration and bacteriological examination only the typhoid bacillus were found, operation could be deferred because such effusions were likely to be absorbed without further trouble. The gall-bladder was comparatively frequently the seat of a typhoid abscess. Sometimes the typhoid bacilli retained their vitality for a long time. A case was on record in which the bacilli retained their vitality in the gall-bladder for seventeen years. The principal surgical complication of typhoid was intestinal perforation, and the large ones called for prompt operation. The important symptoms of this formidable complication were spasm of the rectus muscle, the sudden onset of pain and tenderness and the coincident change from abdominal to thoracic respiration.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending March 14, 1903:

	Cases.	Deaths
Measles	290	13
Diphtheria and croup	376	39
Scarlet fever	319	17[1]
Smallpox	2	..
Varicella	120	..
Tuberculosis	279	152
Typhoid fever	63	8
Cerebrospinal meningitis	..	..

The Pill and the Bill.—

An angel's face the Doctor wears
When first his aid is sought;
A God-like countenance he bears
Soon as the cure is wrought

But when his little bill he makes
And seeks his humble fee,
A form most terrible he takes,
A horrid Devil he.

—Prof. J. Stuart Nairne, Glasgow, Scotland.

Do Nasal Diseases in Any Way Predispose to or Cause Pulmonary Disease?—E. L. Shurly does not believe that nasal diseases are constitutional in the sense that most systemic diseases are because they are not accompanied with the hemic or lymphatic disorders on the one hand, nor with the pyretic and other frank disturbances of the system on the other, which characterize either the slowly developing, or more acute so-called infectious diseases: in short, there are no constitutional disturbances not traceable to the sensory nervous system which can be laid to the ordinary group of chronic nasal disease—rhinitis, ozæna, or kindred morbid states—excepting, of course, the suppurative diseases of the accessory cavities. Moreover, very many nasal diseases depend wholly on local conditions, such as spurs, old fractures, adenoids, neglected states of the ethmoid regions, etc. Hence it does not seem feasible to regard chronic nasal or nasopharyngeal disease as at all particularly concerned in the development of chronic pulmonary disease. Concerning the acute pulmonary disease, however, this strict conclusion would seem to require modification, because intranasal deformities, chronic and atrophic rhinitis, enlargement of adenoid

tissue at the vault of the pharynx, etc., certainly are conditions, which invite attacks of influenza and tonsillitis—so-called "colds," which, in turn, do frequently descend (so to speak) by continuity to the lower respiratory tract, thus producing bronchitis or the pneumonias, besides rendering the subject possessing them more liable to diphtheria and measles.—*International Medical Magazine.*

Oxygen and Muscle Metabolism.—(1) The progressive loss of irritability in a surviving muscle is markedly delayed by an abundant supply of oxygen. (2) The advent of natural rigor mortis is delayed, apparently indefinitely, by the same influence, even when special means are taken to hasten it. (3) These preservative actions of oxygen appear to be independent of the shape of the muscle and its surface relations, and no confirmation has been found for the view of Hermann that the action of oxygen on muscle-substance is two-fold, one effective at the surface, the other, opposite in character, effective below the surface. (4) The phenomena of fatigue resulting from active contractions in an excised muscle are, irrespective of its shape, diminished in intensity and in rapidity of onset, by an adequate contemporary supply of oxygen, and marked recovery from the effects of fatiguing contraction may be seen in a muscle deprived of nutriment but exposed freely to oxygen. (5) The survival discharge of CO_2 from an excised muscle is increased during periods of contraction in the presence of abundant oxygen, the increase being proportionate, or roughly so, to the number and degree of the contractions. In agreement with observations already published, this additional yield of CO_2 accompanying contraction is absent or incomplete in the case of a muscle made to contract in air or nitrogen.—W. M. Fletcher, *in Journal of Physiology.*

An Early Case of Intussusception—Reduction by Water Pressure.—A. Jeffreys Wood reports the case of a little girl of sixteen months who was taken with sudden abdominal pain followed by shock. A diagnosis of intussusception was made, and it was decided that owing to the recent nature of the case, and the typical position of the trouble in the region of the ileocæcal valve, an attempt to reduce the bowel with water pressure was justifiable. The child was anæsthetized and water was run into the bowel by means of a No. 12 Nélaton rubber catheter, attached to a douche can raised three feet above the buttocks; the bowel filled rapidly, and blood and mucus appeared with the water, when it was expelled. The procedure was repeated and the tumor could then no longer be felt. The colon was then irrigated with a catheter attached by a rubber tube to a glass funnel. The color of the face improved immediately after the second flushing, and the rate of the pulse fell to below 100, and its volume improved very markedly. A sound sleep of two and a half hours followed the reduction. On waking, the child was very bright and played with her picture book. A week later there were no signs of recurrence.—*Intercolonial Medical Journal of Australasia.*

Note on the Treatment of the Chancre.—I. Dyer says that ordinarily cleanliness and some mild astringent application, as black wash or yellow wash, or dusting powders with antiseptic qualities are sufficient to protect the ulcer until it heals of its own accord. Powders of service here are nosophen, compound stearate of zinc, bismuth with perhaps 1 per cent. of salicylic acid added, etc., as indicated. The only indication for internal treatment is with such agents as will help to establish the resistance of the individual until such time as he is ready to accept the diagnosis of syphilis, because proven, when he can take proper medicine for the disease. To anticipate the diagnosis, to do anything which will preclude it, as does the early administration of either mercury or iodide, is wrong, illogical, and unjustified. The very eruption of macular syphilis, which is usually the first of the skin evidences, is the attempt of Nature to eliminate the poison; then is the time to help Nature and the patient with internal treatment which has the chief quality of eliminative process.—*New Orleans Medical and Surgical Journal.*

Cutaneous Affections in Relation to Life-insurance Examinations.—Joseph Zeisler says that the salient point must always be the determination whether a skin disorder is merely a local affair, or dependent upon some constitutional disturbance of more or less import. Diabetes may cause general or localized pruritus, furunculosis, gangrene, and a rather rare dermatosis known as dermatitis diabetica. Whenever psoriasis occupies a very large area, or has become generalized, it should form a sufficient ground for rejection. In fact, any dermatosis which covers practically the whole surface should be regarded with suspicion as to its influence upon longevity. This applies particularly to eczema, lichen ruber, pityriasis ruber, and pemphigus. In case of the last-named disease, even in its initial stage, when there may be found an occasional bulla only—on the chest, for instance—the gravest apprehension is justified. Lupus is fortunately rare in this country, and frequently remains localized when it does occur. A consideration of syphilis in its relation to life insurance would deserve a special chapter; the examiner should be capable of making a diagnosis without the aid of the patient. Many constitutional disturbances may be discovered by examining the tongue and the nails. The author holds that a thorough inspection of the whole integument should be a part of every examination, and will often reveal important stigmata.—*The Medical Examiner and Practitioner.*

Notes on a Case of Neuropathic Arthropathy.—A. E. Garrow reports the case of a woman who for several years had suffered from pain in the back, girdle sensations, twitchings in the limbs, dragging of the feet in walking, attacks of involuntary contractions of the legs, chiefly in adduction, tingling in feet and toes, and incontinence of urine and fæces. When admitted to the hospital she was unable to walk, and could assume a sitting posture in bed with great difficulty, owing to spasm of the lower limbs on attempting to move. The case was diagnosed as one of transverse myelitis. A few days after admission she complained of a heaviness in the left shoulder; the shoulder and arm were found to be much swollen and distinctly hotter than the forearm. The swelling of the shoulder was spherical and tense, the bulging being especially marked beneath the outer extremity of the pectoralis major, but less marked behind. There was no pain on active or passive motion. The restricted movement was evidently due to the tension of the joint and the infiltrated tissues. There was no evidence of muscular spasm. Treatment consisted in applying hot fomentations of lead and opium, and fixing the joint by means of an internal lateral splint. The tension is rapidly becoming less, and the infiltration is being absorbed.—*The Montreal Medical Journal.*

The Galvano-cautery in Hypertrophic Rhinitis.—J. E. Schadle says that the shape of the distal end of the galvano-cautery knife is of the greatest importance in the operation. If the platinum loop is not evenly hammered, and it usually is not, as obtained from the instrument-maker, being too thin at or near the point and too thick near its insertion into the copper conductors, it cannot be heated evenly to the necessary temperature of a bright cherry red. Thus hemorrhage will result from the too hot point and from sticking to the too cold head. This defect is due to the fact that the thinner end of the knife offers more resistance to the current than the lower, thicker portion, and it therefore follows that the loop should be shaped rather by filing than by hammering. The different shapes of knives to be used are largely due to the fancy of individual operators and instrument-makers, and should not be considered, because any well-constructed platinum loop can be bent into any shape to suit a particular case. The only point upon which he would lay stress in advising as to the purchase of a

galvano-cautery instrument is to see that the handle and the conductors carrying the platinum loop should be sufficiently large and capable of carrying the required current long enough without becoming even warm.—*International Medical Magazine.*

The Salicylates in Acute Rheumatism.—H. W. Syers says that his experience of salicylates in the treatment of rheumatic fever has been that the benefit is definitely confined to the relief of pain, and, to a certain extent, to the reduction of temperature. That the course of the disease is in any way abbreviated, or that the tendency to peri- and endocarditis is at all lessened his experience has been very far from substantiating. He is disposed to think that the liability to heart involvement is rather increased than diminished by the employment of this remedy. The pain-alleviating power of the drug is, however, so great and so rapid that it is impossible to decry its efficiency. This is a different matter from regarding the treatment as a specific in acute rheumatism. The duration of the malady is not lessened, the liability to heart complications is not diminished, and, most assuredly, the chance of relapse is just as great, if not greater, than when the affection is treated otherwise than by the administration of salicylates. According to recent researches by A. Menzer, who is a strong supporter of the bacterial origin of acute rheumatism, salicylic acid is neither a direct bactericide, nor does it possess the power of increasing the bactericidal action of the blood.—*Treatment.*

Does Early Treatment of Acute Inflammation of the Middle Ear Prevent the More Serious Complications?—E. L. Meierhof reports four cases in which the symptoms for a long time did not point to involvement of the mastoid, but as no improvement followed the treatment applied, the mastoid was opened and found to be filled with pus. He concludes that the indications for operation will be found in a much larger number of cases than previously, until it will even be done for profuse suppuration of the middle ear of a few weeks' duration, even though there is no pain, and thus do away with the more chronic processes and the need of radical operations. His experience, however, has been that for the prevention of chronic suppuration without mastoid symptoms, the minor treatment, with few exceptions, has yielded all that could be desired, and that a very few have required the major operation when the cases have had the benefit of early expert treatment.—*Archives of Otology.*

Appendicular Dyspepsia.—James B. Eagleson has come to the following conclusion: There is a form of dyspepsia of appendicular origin. In one class of cases it is largely reflex, depending upon the presence of a fecal concretion within the organ, or a slight ulceration or catarrhal condition of its mucosa. In another class of cases it is mechanical, caused by an obstruction or irritation resulting from adhesions following a more or less acute attack of inflammation at some previous time. These cases are cured by surgical interference. In all cases of chronic dyspepsia the condition of the appendix should be carefully investigated. When a chronic dyspepsia has resisted all medicinal treatment and its origin has been diagnosed as appendicular, an operation should be advised. —*Northwest Medicine.*

Hysteria Simulating General Paralysis.—F. J. Collet and Jean Lepine report the case of a man of thirty-four years who, after a severe mental suffering, was affected by temporary loss of consciousness, extreme anarthria, without mutism, aphasia, nor agraphia; awkwardness in the use of the right hand, with preservation of muscular force and left glossolabial hemispasm. There was persistence of slight anarthria after disappearance of the other symptoms. Several relapses occurred without loss of consciousness. There were transitory signs of general paralysis, loss of memory, trembling of the tongue, etc. Rest in bed, mental relaxation, abstinence from alcohol, and hydrotherapy brought about a complete cure of what the author considers was rightly diagnosed as hysteria.—*Revue de Médecine.*

Medical Senators in France.—At the recent election for the French Senate, eighteen members of the medical profession were successful. Among these are M. Combes, the Premier, who was returned by two departments; Dr. Peyrot, surgeon to the Lariboisière Hospital, and a member of the Académie de Médecine, and Dr. Jean Bayol, formerly a medical officer of the French navy, Lieutenant-Governor of Senegal, and Governor of French Guinea. Among the unsuccessful condidates were Professors Carnil and Pozzi. —*British Medical Journal.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ending March 14, 1903:

SMALLPOX—UNITED STATES.

			CASES.	DEATHS
Alabama, Mobile	Feb 28–Mar. 7		11	.
California, Fresno	Feb. 1–28		23	
Los Angeles	Feb. 22–28		4	
Sacramento	Feb. 22–28		3	.

RENAL DECAPSULATION FOR CHRONIC BRIGHT'S DISEASE.*

By GEORGE M. EDEBOHLS, A.M., M.D.,
NEW YORK.

PROFESSOR OF THE DISEASES OF WOMEN, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; SURGEON TO ST. FRANCIS HOSPITAL; CONSULTING GYNECOLOGIST TO ST. JOHN'S HOSPITAL, YONKERS, N. Y., AND TO THE NYACK HOSPITAL, NYACK, N. Y.

The first operation ever undertaken upon the kidneys with the deliberate purpose of bringing about a cure of chronic Bright's disease was performed by the writer on January 10, 1898. This operation consisted in extensive decapsulation, followed by fixation, of both kidneys. The patient, a girl of twenty at the time of operation, has since married, is now five months pregnant, and remains permanently cured of her former chronic Bright's disease, very frequent examinations of the urine made during the past five years invariably showing normal conditions, and her general health since operation being excellent. This operation, together with a report of five preceding operations which gradually led up to it, was published in the *Medical News*, April 22, 1899. In all of these cases the kidneys were movable as well as affected with chronic Bright's disease, and the operation, as already stated, consisted in extensive decapsulation, followed by fixation of the kidney. At the time, the idea that the cure of chronic Bright's disease in these cases was mainly, if not altogether, due to correction of the position of the kidney by fixation, dominated my mind. Further experience, however, and observations made upon the occasion of second operations upon kidneys previously anchored at periods more or less remote from the first operation, gradually evolved the conviction that the decapsulation was mainly responsible for the good results obtained, and that renal decapsulation acted by removing a barrier in the shape of the capsule proper to the creation of a new and increased and more active blood supply to the diseased kidney. The removal of this barrier by renal decapsulation is followed by the formation, on the most extensive scale possible, of new vascular connections between the kidney and its fatty capsule. The removal of inflammatory products by absorption, and the new formation of epithelium capable of carrying on the functions of secretion—in other words, improvement and restoration of the health of the kidney—are the direct results of this increased blood supply and improved circulation of the kidney.

These views were announced in a second publication in the Medical Record, May 4, 1901, and, based upon them, I advanced the proposition to treat chronic Bright's disease, *as such*, by renal decapsulation, whether the affected kidney be found normally situated or displaced.

The proposition as well as the performance of renal decapsulation for the cure of chronic Bright's disease constitute entirely new departures in medicine, original with the writer. The subject was further elaborated, and all the writer's operations upon kidneys affected with chronic Bright's disease were reported in detail in the Medical Record, December 21, 1901. The operations numbered nineteen, and included eight cases in which a cure of chronic Bright's disease lasting at the time of report from one to over eight years after operation was obtained. To these publications, and to a résumé prepared by the writer and published in the Medical Record, April 26, 1902, the reader who may be interested is referred for fuller details regarding the developmental stage of the surgical treatment of chronic Bright's disease. In this publication, also, the literature of the subject was fully cited and discussed. Included in a continuation of the literature appended to the present paper will be found references to one or two publications more or less pertinent which escaped my attention in the preparation of my last article, and which are here listed for the sake of greater completeness.

During the year 1902 there appeared in various medical journals accounts of isolated cases in which my operation of renal decapsulation for chronic Bright's disease was performed by various surgeons. These cases will be noticed again further on. There also appeared during the same year several communications of a practical character by Israel, Pousson, Lennander, Rovsing, and Edebohls, on topics more or less related or germane to the subject of the surgical treatment of chronic Bright's disease, although not concerning themselves directly with the surgical treatment of chronic Bright's disease *as such*. Israel indeed, as I have already pointed out in a previous publication[7], emphatically disclaims any intention or desire on his part to bring about an era of the surgical treatment of chronic Bright's disease, and Pousson,[17] after repeating his previous experiences, already repeatedly detailed at great length in numerous prior publications, adds one or two new cases of surgical interference on various special indications, and avers that he has never operated for the cure of chronic Bright's disease as such. It may be added, however, that Pousson has recently become a convert to renal decapsulation, although he appears not as yet to have performed the operation. Lennander[14] reports three cases, additional to five previously reported by him, of suppurative pyelonephritis treated surgically by resection of the kidney and drainage. Rovsing[19] fully details seventeen cases in which surgical intervention upon the kidneys was undertaken to meet a variety of indications, and Edebohls[8] reports upon renal decapsulation as performed by him upon six patients for conditions other than chronic Bright's disease. In all of the cases reported by the writers mentioned operation upon the kidney was undertaken primarily for the relief of grave accidental complications of acute or chronic nephritis, or for renal conditions admittedly requiring surgical interference, and complicated by nephritis, such as purulent infection of the

*Read before the Medical Association of the Greater City of New York, February 9, 1903.

kidneys, renal hæmaturia, renal pain, and suppression of urine.

The publications already commented upon deal with the subject of chronic nephritis upon the basis of practical operative experience. In addition there have appeared during the year 1902 a number of purely theoretical papers, several of them of pretentious character, touching more or less upon the same subject. As these theoretical papers add little or nothing of material value to either our knowledge or experience I have omitted citing a reference to them.

Since the announcement of my proposition to treat chronic Bright's disease by decapsulation of the kidneys, reports of nine cases operated upon after my method by seven different American surgeons have found their way into the medical press. Cabot[1] and Elliott[9] each report two cases; Primrose,[18] Lyman,[15] Guitéras,[11] and Hanchett,[12] one case each. Guitéras reports, in addition, a unilateral nephropexy with extensive denudation performed upon a kidney the seat of chronic nephritis. Gradle[10] reports a case operated upon by Ries, and Caillé[2] details the history of one of his cases operated upon by the writer, and included in my summary to follow. Primrose performed decapsulation upon one kidney only, having at a previous date performed nephrotomy upon the opposite side. Lyman, Cabot, Guitéras and Elliott decapsulated both kidneys at one sitting, while Hanchett and Ries operated upon one kidney at a time. The period of observation intervening between operation and report in those who survived the operation is, however, too short to permit of any deductions of great practical value. In addition to the above published cases the writer has knowledge of quite a number of unreported cases of renal decapsulation for chronic Bright's disease performed during the past year by a number of surgeons other than those named.

My personal experience with operations upon kidneys the seat of chronic Bright's disease, from the date of my first operation of this character in 1892 up to and including the year 1901, was reported in detail and tabulated in my paper in the MEDICAL RECORD of December 21, 1901. The list embraces nineteen cases. During the year 1902 I have operated upon thirty-two additional cases of chronic Bright's disease, in each of which I performed decapsulation of both kidneys at one and the same sitting. My total experience, therefore, up to the end of the year 1902, embraces fifty-one cases.

Of the fifty-one patients, twenty-nine were females and twenty-two were males. With the exception of a girl of four and a half years, all the patients were adults. The other extreme of age was represented by a man of sixty-seven, and the average age of the fifty-one patients was thirty-four years. Twenty-four of the patients were operated upon at the Post-Graduate Hospital, thirteen at St. Francis Hospital, ten at their homes, and four in a private sanatorium.

The basis for the diagnosis of chronic Bright's disease in the nineteen cases already reported was detailed in my previous paper.[5] The thirty-two cases operated upon during 1902 were all cases of far advanced chronic Bright's disease. In all of them the clinical history, the physical examination of the patient, and the chemical and microscopical examination of the urine left no room for doubt as to the diagnosis. All of the patients knew that they were the victims of chronic Bright's disease prior to consulting me with a view to operation. While with the great majority of the patients, gradual loss of strength, increasing pallor, uræmic headaches, vascular and digestive disturbances, dropsy and other manifestations of chronic Bright's disease led to medical consultation and the discovery of the kidney affection, quite a number first learned upon application for life insurance that they were the victims of the disease. Others again, more or less suddenly and more or less completely, lost their eyesight, and derived their first information of the diseased condition of their kidneys from ophthalmoscopic examination, which disclosed the characteristic lesions of the retina due to chronic nephritis. A few obtained their first knowledge of the existence of chronic Bright's disease in their persons as a result of a sudden attack of paralysis. The length of time intervening between the first recognition of chronic Bright's disease and the date of operation, is noted in the clinical histories of forty-one of my fifty-one patients. In the remaining ten the existence of the kidney affection was either noted but a short time before operation, or no exact data bearing upon the point in question could be obtained. In these forty-one patients Bright's disease was known to be present before operation for periods varying between one month and nineteen years, the average duration for the forty-one being three years and four months, while for the thirty-two cases operated upon in 1902 it was fully four years. It is quite safe to say, however, that in each case the disease existed for a longer or shorter period of time prior to its first recognition, and that renal decapsulation was performed in each case at a considerably more advanced period of the disease than that indicated by the above figures.

Of the thirty-two cases of advanced chronic nephritis operated upon during 1902, very few, indeed, were uncomplicated or but slightly complicated cases of chronic Bright's disease. Nearly all presented minor, greater, or extreme cardiac and vascular degenerations: arteriosclerosis, hypertrophies of all degrees up to the point of non-compensation and beginning predominant dilatation, pericarditis and endocarditis. Pleuritis and hydrothorax as complications were by no means rare, while one patient had cavities in both lungs, and two patients suffered from cirrhosis of the liver in addition to chronic Bright's disease. The cerebral and ocular complications were represented by hemiplegias due to changes in the cerebral vessels, to embolism, thrombosis, etc., and by the characteristic retinal lesions.

The clinical diagnosis in each case was borne out by the conditions presented by the kidneys at operation, the characteristic pathological changes due to the presence of chronic Bright's disease being readily and unmistakably appreciable by sight and touch. Occasionally the diagnosis received a rather superfluous corroboration from the microscopical examination of a minute piece of kidney tissue found adherent to the removed capsule proper. As to the propriety and justifiability of deliberately removing a piece of tissue from a kidney, the seat of evident chronic Bright's disease, merely for the purpose of microscopical examination, I have already elsewhere expressed myself negatively.

The division or classification of cases of chronic Bright's disease, according to the pathological changes found in the kidneys at operation, into parenchymatous, interstitial and diffuse chronic nephritis, a classification advanced in a former paper[5] as the most practical for our purposes in the present state of our knowledge of the subject, has been maintained and applied to the cases operated upon in 1902. The reasons and basis for the above classification were also sufficiently set forth in the paper mentioned, and need not be here repeated.

Of the entire number of fifty-one patients with chronic Bright's disease operated upon, twenty-nine had chronic interstitial nephritis, fourteen had chronic diffuse nephritis, and eight had chronic parenchymatous nephritis. In all the cases of chronic diffuse and of chronic parenchymatous nephritis both kidneys were affected, though not always in equal degree on both sides. In the twenty-nine cases of chronic interstitial nephritis the disease was limited to one kidney in no less than nine instances, affecting both kidneys of twenty patients only.

These nine cases of unilateral chronic nephritis were detailed in my paper of a year ago, and excited a good deal of surprised comment and even of incredulity and denial. While surgeons of greater experience in renal surgery were, as a rule, ready to accept my findings as correct, in view of operative experiences of their own pointing in the same direction, the contention was made by some clinicians of the highest rank that chronic Bright's disease is always bilateral. It appears to the writer that these two different positions and views are not so difficult of reconciliation as may appear on the surface. Chronic Bright's disease, *as such and in itself*, rarely or never causes death when limited to one kidney; in fact its unilateral existence, save in very exceptional instances, goes practically undetected during life unless accidentally revealed either by urinary examination or by the knife of the surgeon. As long as one kidney is healthy, and performs its functions, the general health need not suffer to an extent sufficient to induce consultation with a physician, even though the second kidney be seriously diseased. It has been abundantly proven that one-third of the total kidney substance possessed by man is sufficient to sustain life. That the disease in its further development becomes invariably bilateral is probably the truth. Surgeons, in their operative work, have now and then met the disease in its earlier stages unilaterally; physicians derive their convictions from the fact that the patient comes under their professional care in the later stages, when the disease has become bilateral, and from the observation that the disease, as found in the dead-house, is practically always bilateral. Bright's disease, like everything else, must have a beginning; that it may make decided progress in one kidney before attacking the other, I, in common with other surgeons, consider proven. I have not met with any cases of unilateral chronic nephritis in my surgical work of 1902 simply because all of the cases operated upon during that year were cases of *very* far-advanced chronic Bright's disease.

A rest in bed of a few days to a week, according to the special indications in each case, is advisable by way of preparation for every patient about to undergo the operation of renal decapsulation for chronic Bright's disease. In all cases of advanced chronic nephritis, almost without exception, the heart is more or less involved, and favoring the organ for a few days prior to the ordeal betters its chances of standing the strain to which the operation necessarily puts it. The rest in bed also minimizes the eliminative work to be performed by the kidneys, resting those organs, and is further utilized for measurement of the daily amount of urine, for chemical and microscopical examination of that secretion, for regulation of the food and drink ingested, for the administration of urotropin, if called for by the presence of pus and bacteria in the urine, for the exhibition of cardiac and vascular regulators like strychnine, digitalis, glonoin, etc., according to the indications in each particular case. With proper preliminary preparation of the patient, the probabilities of a successful issue of the operation are materially increased.

The writer's operation of renal decapsulation for chronic Bright's disease has already been described at sufficient length in previous publications,[4] [5], [8]. It only remains to call attention to one or two matters of practical experience which larger opportunities have developed.

Presuming always a reasonable familiarity and experience with renal surgery in general on the part of the operator, there are three conditions, the presence or absence of which makes renal decapsulation a more or less difficult or a comparatively easy operative procedure. The first of these conditions, great length and obliquity of the twelfth rib, with narrowness of the space between last rib and ilium, can be materially overcome by proper posturing of the patient, as on the author's kidney air-cushion, for instance, and by a slight modification of the obliquity of the incision. The second factor upon which the ease or difficulty of the operation depends is mobility of the kidney to be operated upon, or its firm attachment in its normal site well up beneath the ribs. In the latter event only a small surface of the lower pole of the kidney can be exposed, and even this meagre approach to the kidney is sometimes accomplished only under the greatest difficulties. The procedure under these circumstances is to incise the capsule proper at any portion of the surface of the kidney that can be reached, to seize the edges of the capsule wound with forceps, and to complete the separation of the capsule proper from the kidney, in the depths of the wound. For detaching the capsule proper from the kidney, especially if the separation must be done in the depths of the wound beyond aid from the sense of sight, I have found the smooth index finger of the rubber-gloved hand the *very* best instrument. The third condition influencing the facility of renal decapsulation is connected with the more or less firm attachment of the capsule proper to the kidney. In the parenchymatous and diffuse forms of chronic nephritis the capsule will generally be found easily separable from the kidney, while in cases of chronic interstitial nephritis the connections between capsule proper and kidney are frequently of a firm, densely fibrous character. As the kidney tissue is generally very brittle and friable as the result of long-standing inflammation, great caution and gentleness are necessary to avoid the danger of tearing away pieces of the kidney or of fracturing the organ during attempts at decapsulation. The views upon renal tension as an element in chronic Bright's disease which I expressed in a previous publication[6], have but received confirmation as the result of increased experience and observation.

The difficulties of renal decapsulation arising from one or both of the conditions last named receive illustration from two experiences of other operators which have casually come to my knowledge. A colleague who witnessed a renal decapsulation, or rather an attempt at renal decapsulation for chronic Bright's disease, by a surgeon of his acquaintance, informed me that the surgeon, after cutting down on both sides, was unable to find, let alone explore or decapsulate, either kidney, the organs being probably greatly diminished in size as a result of the chronic interstitial nephritis diagnosticated before operation. The wounds were closed, and the patient and his friends were left under the impression that decapsulation had been performed. I have in my possession a letter from a professor of surgery in one of our Western medical colleges detailing his first attempt at renal decapsulation. Unable to bring the kidney into view, he introduced a sharp

curette into the depths of the wound and, at long range and beyond sight, scraped the capsule proper from the kidney all around at haphazard and as best he could. It is sickening to contemplate the laceration and destruction of kidney substance which must have accompanied this procedure performed upon a patient who, on account of the presence of chronic Bright's disease, could ill afford to spare any portion of his renal tissue.

Renal decapsulation for chronic Bright's disease should for the present, therefore, be undertaken only by surgeons more or less familiar by practical experience with renal surgery in general. Any other course must tend to bring upon the operation unjust and undeserved disrepute. One surgeon informed me that he had performed four renal decapsulations upon four victims of chronic Bright's disease, each of the four dying promptly after operation. He added that these four operations represented exactly the half of his total experience in renal surgery.

The danger in operations of every kind, renal operations included, upon patients suffering from chronic Bright's disease is, broadly speaking, greater from the anæsthetic than from the operation itself. In renal decapsulation, fortunately, the moderate abstraction of blood directly from the kidneys accompanying and forming a necessary part of the operation, counteracts to a great extent the congestive effects of the anæsthetic upon the kidneys. Nevertheless, it is *very* important that the operation should never be too prolonged, and I should say that one hour should be regarded as the limit of time to be allowed for decapsulation of both kidneys for chronic Bright's disease. In more than one-half of my operations I have required no longer than half an hour, counting from the first incision to complete closure of both wounds ready for the application of dressings. It is a realization of the necessity of curtailing the duration of the anæsthesia that has prompted the expedient of a team operation, two surgeons operating at the same time, one on either kidney. Personally I feel that, operating singly, I can decapsulate both kidneys in the same space of time that I would require for one kidney if handicapped by the presence of a second surgeon and his assistant working simultaneously upon the fellow organ. Each surgeon and his assistant must necessarily be more or less in the other's way. Another expedient that has been adopted for the purpose of lessening the length of anæsthesia is to operate upon one kidney at a time. Such a course, however, can only be condoned in a surgeon who is not sufficiently practised in renal surgery to decapsulate both kidneys within the hour, since it is evident that on account of the time required for inducing full anæsthesia before each operation, the total duration of anæsthesia for two operations will be greater than that required for decapsulation of both kidneys performed at the same time.

Ether has continued to be a satisfactory anæsthetic and, preceded by nitrous oxide, was administered to all but three of the thirty-two patients operated upon in 1902; these three patients were anæsthetized by Dr. Thomas L. Bennett with nitrous oxide and oxygen.

As I have already stated, in all my renal decapsulations of 1902 both kidneys were invariably operated upon at the same sitting. All the wounds were completely closed throughout and drainage was entirely dispensed with, except in one case in which a few strands of silkworm gut were left in the wound for a few days to drain off the enormous quantities of serum found at operation in all the tissues of the back as well as in the perirenal fat. Perfect primary union throughout was obtained in all but one of the sixty-four wounds made. In the one exception in which bilateral nephropexy, as well as appendicectomy for chronic appendicitis through the right lumbar wound, were performed in addition to renal decapsulation, a temporary leakage of urine occurred from the surface of the right kidney. The cases of chronic nephritis with infection did just as well in the way of perfect healing of the wounds as the cases of chronic nephritis without infection.

In twenty-seven of the thirty-two patients operated upon in 1902, bilateral renal decapsulation was the sole operation performed. In two patients fixation of both kidneys and removal of the appendix through the right lumbar wound for chronic appendicitis were practised at the same sitting with bilateral renal decapsulation. A third patient had fixation of both kidneys, and a fourth had fixation of the right kidney added to bilateral decapsulation. Upon a fifth patient, finally, whose left kidney was found converted into one huge cyst, left nephrectomy and decapsulation of the right kidney were performed at the same sitting. Nephropexy was added to renal decapsulation in those patients who had both chronic Bright's disease and movable kidney or kidneys, only when the symptoms due to mobility of the kidney or kidneys were so decided as to call urgently for relief. When the looseness of the kidneys produced no symptoms the mobility was disregarded, and the operation was shaped entirely with the view to improvement or cure of the chronic Bright's disease.

Of the fifty-one patients suffering from chronic Bright's disease, upon whose kidneys I have operated during the past ten years, from 1892 to the end of 1902, I have lost all traces of only three. All the rest, forty-eight in number, I have managed to keep in touch with up to death or the present writing. This rare achievement, for as such it will be appreciated by all physicians who have tried to follow their cases through the years, is all the more remarkable in view of the fact that the patients are scattered far and wide, less than one-half of the entire number living in New York.

Of the fifty-one patients fourteen died at periods of time after operation varying between twelve hours and eight years. The following is a brief synopsis or record of the deaths:

Case 3.—Mrs. M. M., aged twenty-eight years, a patient of Dr. R. G. Wiener, was known to have chronic Bright's disease for several years before operation. Operation on the right kidney, May 11, 1893, showed right chronic diffuse nephritis, with formation of a large cyst. Incision of kidney; evacuation of contents of cyst; suture of kidney wound; extensive decapsulation, followed by fixation of kidney. Three years later another surgeon removed the left kidney. For five years more the patient lived with only one kidney, the one originally operated upon by me. At the end of that time a third surgeon performed an abdominal hysterectomy, as a result of which she died, in May, 1901, eight years after my operation upon her right kidney. According to her physician, the nephritis still persisted at her death.

Case 11.—Mrs. S. G., aged twenty-eight years. Operation, extensive decapsulation of both kidneys, followed by fixation, was performed on November 4, 1899, and showed right chronic interstitial nephritis, the left kidney being healthy. The patient died after an operation for ruptured tubal pregnancy exactly one year after my operation. Drs. S. J. Meltzer and J. J. Brettauer, who attended her in her last illness, inform me that there was then no chronic Bright's disease, the urine being perfectly normal.

Case 17.—Mrs. M. S., aged thirty-three years, patient of Dr. T. W. Vardon, Galt, Ontario, Canada. The history of this case was detailed at length in a former paper.[5] Bilateral renal decapsulation was performed upon the practically moribund patient, October 17, 1901, and showed right and left chronic parenchymatous nephritis with infection, pus being abundant in the urine. Both wounds healed by primary union throughout, and the patient improved marvellously and steadily after the operation until December 5, when a severe attack of acute suppurative pyelonephritis supervened, which terminated her life on December 15, 1901, two months after operation.

Case 19.—Miss A. B., aged forty-three years, patient of Dr. F. Schwyzer, suffered from chronic Bright's disease, with cardiac complications, for two years. At the time of operation there existed extreme hypertrophy of the heart, with a double mitral murmur. Bilateral renal decapsulation on December 3, 1901, disclosed far advanced bilateral chronic interstitial nephritis, the kidneys being shrunken to less than half their normal size. Patient left hospital a month after operation, resumed her former dissolute habits, was picked up drunk on the streets a number of times, and finally landed in the Almshouse Hospital, where she died, December 9, 1902, one year after operation. The death certificate gives chronic interstitial nephritis and endocarditis as the causes of death.

Case 24.—A. W. B., male, aged twenty-three years, a patient of Dr. L. B. McBrayer, Asheville, N. C., while in apparent health was stricken suddenly with almost complete blindness on December 21, 1901, when examination of the eyes and urine revealed chronic Bright's disease as the cause. From that date until operation the patient was so blind that he could not find his way about alone in broad daylight. At operation, April 11, 1902, almost total blindness, profound uræmia, enormous hypertrophy with tumultuous action of the heart, and mitral regurgitation. Operation disclosed far advanced chronic interstitial nephritis, the kidneys being contracted to half their normal size. Uræmia gradually deepened after operation, and severe epistaxis, requiring repeated plugging of the nares, supervened on April 18. Patient died on April 19, eight days after operation, of exhaustion and uræmic coma.

Case 27.—V. M., male, aged twenty-one years, patient of Dr. A. P. Dodge, Oneida, N. Y. Albuminuria and general dropsy since December, 1900; retinitis albuminurica, with V=1/200 in either eye, since December, 1901; heart greatly hypertrophied; stenosis of aortic orifice. Operation, on April 16, 1902, showed advanced chronic diffuse nephritis with beginning contraction of the kidneys. For some months after operation the patient did well, gaining markedly in strength, and recovering his eyesight to a very great degree. On November 25, 1902, he had an attack of acute pleuritis, from which he recovered. On December 25, 1902, uræmic symptoms developed. Uræmic coma and epistaxis closed the scene on January 18, 1903, nine months after operation.

Case 29.—A. J., male, aged thirty-four years, a patient of Dr. B. R. Morrow, had chronic Bright's disease for five years before coming under observation. General œdema, bronchorrhœa, bronchial hemorrhages, intense dyspnœa, and uræmic headaches were the main symptoms. At the time of operation enormous hypertrophy of the heart, with beginning dilatation, uræmia, and the hemorrhagic diathesis were the ominous manifestations. Operation not advised, but undertaken at patient's earnest pleading on April 21, 1902. Both kidneys were found shrunken to less than half their normal size as a result of chronic interstitial nephritis. Patient died of uræmia on April 24, 1902, three days after operation.

Case 32.—E. W., male, thirty-two years of age, suffered from chronic parenchymatous nephritis ever since an attack of scarlet fever five years ago. Immense general anasarca and ascites existed, and to relieve the latter the abdomen was tapped five times during the four weeks preceding operation. Renal decapsulation was advised by the surgeons of a hospital of this city of which the patient was an inmate. The surgeons, however, declined to operate themselves, and referred the patient to me. On May 1, 1902, he was transferred in an ambulance from the hospital where he was staying to St. Francis Hospital, where I operated upon him on the following day, May 2, 1902, his desperate condition brooking no delay. The abdomen was relieved of fluid by tapping on the morning of the day of operation. Extreme general anasarca, double hydrothorax, and a feeble heart were present at the time of operation, which showed typical parenchymatous nephritis, the large, white kidney, on both sides. On the fourth day after operation acute fibrinous lobar pneumonia developed in the upper half of the left lung, and the patient succumbed to pulmonary œdema on May 8, 1902, six days after operation.

Case 34.—D. L. D., male, sixty-two years of age, patient of Dr. F. M. Woodard, Springfield, Tenn. Chronic Bright's disease was first recognized on failure of sight in January, 1902, when examination of the eyes disclosed the characteristic retinal changes due to the disease. Moderate cardiac hypertrophy, with an aortic obstructive murmur, were present at operation, which took place on May 26, 1902. Sudden death from acute dilatation of the heart occurred twelve hours after operation.

Case 35.—R. N. H., male, aged fifty-six years. The patient, a physician, first discovered chronic Bright's disease in his person by urinalysis in May, 1901. Œdema of the face and hands, progressive weakness, rapid aging, uræmic manifestations, tumultuous action of the heart, and great dyspnœa on exertion were the main symptoms. Effusion into both retinæ occurred in February, 1902. At the time of operation the heart was markedly hypertrophied, with a systolic bruit over apex, base and aorta, and dicrotism of the pulse, and there existed general arteriosclerosis and extensive neuroretinitis albuminurica. Operation, May 26, 1902, disclosed right and left chronic interstitial nephritis. Improvement followed operation, and was maintained until August, 1902, when he gradually grew worse, intense dyspnœa and inability of the stomach to retain food being the most distressing features until his death, which occurred on November 6, 1902, five months and eleven days after operation.

Case 36.—E. T. W., male, fifty years of age. The patient, a physician, awoke one morning in April, 1901, with partial paralysis of the right half of the body, examined his urine, and found he had chronic Bright's disease. In February, 1902, hemorrhage into the left optic nerve was followed by transient total blindness. Slight œdema and stomach disturbance, progressive loss of strength, urgent dyspnœa, and tumultuous heart action were the chief other symptoms. When he reached my office with his brother, also a physician, he was scarcely able to breathe, even in the upright posture. The lungs were emphysematous, the heart was hypertrophied to the verge of dilatation, with an occasional aortic regurgitant murmur, and the pulse

was dicrotic. He came to me for operation from a great distance, fully aware of his extreme condition and desperate chances. He requested his brother's and my own frank opinions as to how long he was likely to live without operation, and as to his chances of surviving operation, and when we declared two weeks as the probable extreme limit of life without operation, and that death would probably result from operation, he reflected for a moment and then said: "Very well. I am ready and willing to pit two weeks of the life I am leading against even a very small chance of improvement by operation. I wish you to decapsulate my kidneys." The operation was performed on May 26, 1902. Dr. Thomas L. Bennett began the anæsthesia with nitrous oxide gas and oxygen, but was soon compelled to change to ether, and subsequently to chloroform to avoid death on the table. The operation disclosed chronic interstitial inflammation of both kidneys, and was completed in thirty-three minutes. The patient, however, survived but twelve hours, death occurring suddenly from acute dilatation of the heart during an effort at vomiting.

Case 39.—G. F. C., male, sixty-seven years of age. The patient, a physician, had nephrolithiasis and acute nephritis thirty years ago. In 1895 he had a sudden attack of hemiplegia due to cerebral embolism, the result of a cardiac lesion, and was paralyzed on one side of the body for nearly a year. Retinitis albuminurica and chronic Bright's disease were discovered in June, 1901. Hypertrophy of the heart, with beginning dilatation, mitral regurgitation, and general arteriosclerosis were the unpromising features of the case. In spite of the unfavorable outlook, the patient, a life-long personal and professional friend, insisted that he was entitled to the chance afforded by operation, and demanded that I perform it. Operation on June 14, 1902, showed bilateral chronic diffuse nephritis. Gas and ether were administered by Dr. Bennett. Left hemiplegia of cerebral origin developed on the day following operation; heart failure threatened from the very beginning, and the kidneys did not act satisfactorily, only 640 c.c. of urine being passed during the fifty-six hours the patient lived after operation. In spite of all our efforts the patient died of uræmia and heart failure on June 16, 1902.

Case 40.—C. C., male, twenty-nine years of age, first consulted me on March 7, 1902. Chronic Bright's disease was discovered six months previously; shortness of breath and growing weakness were the chief symptoms. Patient has just passed through a mild attack of typhoid fever, which began nearly two months ago. There was immense hypertrophy of the heart, with violent and irregular thumping (galloping heart), and extreme displacement of the apex beat to the left. The patient postponed operation, and in April, 1902, had a severe attack of diphtheria. Following this, great œdema of the feet and abdominal dropsy developed. The patient returned to my office three and a half months after his first visit, and requested that operation be performed before I sailed for Europe on my vacation. Decapsulation of both kidneys was performed on June 26, 1902, after consultation with Prof. A. Caillé, who considered that the heart was concentrically hypertrophied and would stand a narcosis. Chronic interstitial nephritis was found on both sides, the right kidney being contracted to one-half and the left to one-third the normal size. This patient never did well after operation, and died of dilatation of the heart on November 1, 1902, a little over four months after operation.

Case 47.—F. G. C., male, twenty-three years of age, a patient of Dr. Russell G. Floyd, Eureka Springs, Ark., had typhoid fever in 1893, and has never been strong since. For the past two years loss of strength, some œdema of face, digestive disturbances and uræmic manifestations were his chief symptoms. Urinalysis in December, 1901, revealed the existence of chronic Bright's disease. There was general arteriosclerosis; the heart was greatly hypertrophied, and a harsh systolic bruit was present over the aortic orifice. Operation November 26, 1902. The right kidney was first cut down upon, and found contracted to less than half the normal size by chronic interstitial nephritis. The left kidney was next exposed, and found converted into a huge cyst, with no remnants of normal kidney structure. The renal cyst was enucleated and removed entire. The uræmia present at the time of operation gradually deepened, although a fair quantity of urine was passed daily, and the patient died in uræmic coma on December 11, 1902, fifteen days after operation.

Two patients, therefore, died an accidental death, one patient died of acute suppurative pyelonephritis, one of endocarditis, five of uræmia, one of pneumonia, three of acute dilatation of the heart, while in one case death was due to a combination of uræmia and cerebral hemiplegia.

Of the fourteen deaths seven occurred at periods remote from operation varying between two months and eight years, the average duration of life after operation in the seven cases being one year and eight months.

The remaining seven deaths followed operation at periods varying from twelve hours to fifteen days, and represent the operative mortality in my fifty-one cases, which may therefore be stated as $13\frac{2}{3}$ per cent. Three of the seven deaths representing the operative mortality were due to uræmia, two to acute dilatation of the heart, while one was caused by pneumonia, and one by combined uræmia and cerebral hemiplegia.

In judging my mortality, the fact must be taken into consideration that, for one reason or another, I was compelled to accept cases for operation in which the fatal outcome was an almost foregone conclusion. Patients, as well as their physicians, both sometimes represented in one person, insisted that inasmuch as the precise limit beyond which operation could no longer avail to improve the condition of their kidneys was as yet unknown, they were entitled to the benefit of the doubt, and requested, or even demanded, operation. On the grounds of ordinary humanity the request could scarcely be denied, the more so as a number of my patients in whom the chances before operation seemed equally desperate with those of some of the patients who died, had made unexpected and surprisingly good recoveries. Thus it has happened that I have, either willingly or unwillingly, operated upon every patient who came to me for operation except in two instances. In one of them the day was set for operation; the patient's heart acted so poorly, however, that death on the table seemed inevitable. To the patient's keen disappointment the operation was declared off. That very night, seven hours after the date set for the operation that was to have been, the patient died suddenly of acute dilatation of the heart. A second patient who desired operation, but whom I advised not to undergo it, and who accepted my advice, died two weeks after I first saw him.

As already stated, the precise limits beyond which renal decapsulation can no longer avail to save the patient's life cannot as yet be positively stated. The complications of chronic Bright's disease are so numerous, and manifest themselves in such vary

ing combination and severity in different patients, that for the present each case must be judged upon its merits. In advising for or against operation in any given case much will depend upon a careful consideration of the general condition of the patient, as ascertained by a searching physical examination, as well as upon a critical chemical and microscopical examination of the urine.

Derangements of the heart and of the vascular system most frequently present problems the solution of which will influence our advice for or against operation. A certain degree of cardiac hypertrophy and degeneration goes with every case of chronic Bright's disease, and if uncomplicated, or not too greatly complicated, by other changes in the heart and vascular system, does not contraindicate operation. Indeed, renal decapsulation has proven a boon to several patients not alone in improving the work of their kidneys, but also in secondarily diminishing the cardiac hypertrophy dependent upon chronic Bright's disease. When, however, the cardiac and vascular changes have advanced too far and become too widespread ever to be made good, or even improved, the dangers of the operation itself are so vastly increased that it is not worth the patient's while to take the risk. For what will it avail the patient if the work of his kidneys is more or less improved, if, after all, in the natural course of events, he must soon die of incurable disease of the heart and blood vessels? A patient with chronic Bright's disease who has passed the age of sixty should always be carefully investigated before an operation is decided upon. The changes produced in the blood vessels by advancing years, added to those the result of chronic Bright's disease, constitute a serious handicap for the patient. Age, however, is a relative matter, and a man of seventy may have a younger heart and younger blood vessels, in fact may *be* younger, than another of fifty or, for that matter, of forty years. A more extended experience with renal decapsulation, however, is necessary before we can decide positively, in any and every given case of chronic Bright's disease, whether the patient may still hope for cure or improvement from operation, or whether he must be abandoned to his fate.

Bilateral renal decapsulation could be performed by an expert in renal surgery upon one hundred perfectly healthy human beings without the necessity of losing a single life. This is proven by comparison with the statistics of bilateral nephropexy, a more trying surgical procedure, often performed on patients very much run down and sometimes, in addition, upon kidneys not entirely healthy. Of seventy-three patients in whom I anchored both kidneys at one sitting, *i. e.* performed extensive renal decapsulation *and* fixation, only one died as the result of operation. The mortality attending renal decapsulation for chronic Bright's disease will, therefore, prove to be the mortality of the disease itself, and of its attendant complications, rather than that of the operative procedure undertaken for its relief.

The writer has been rarely and extremely fortunate in being able to follow up all but three of the fifty-one patients with chronic Bright's disease upon whose kidneys he has operated. The entire fifty-one cases may, for purposes of studying the final results, be divided into two categories; those cases operated upon prior to July 1, 1902, forty in number, and those cases operated upon during the past seven months, numbering eleven.

The forty cases in each of which more than seven months have elapsed since operation are the only ones that may be considered available for estimating the final results. Of these forty patients thirteen have died since operation and three have been lost sight of, leaving twenty-four patients available for a study of the therapeutic results of renal decapsulation for chronic Bright's disease.

Before proceeding to an analysis of the therapeutic results obtained in these twenty-four cases, some general considerations bearing upon the question of what constitutes cure and improvement in chronic Bright's disease are in order. It will, likewise, be necessary to define the standards by which cure or improvement is to be judged.

In the first place, the natural history and course of chronic Bright's disease, either untreated or treated by methods other than operative, must be taken into account. It is a well-established fact that patients suffering from chronic Bright's disease often experience temporary improvement, both as regards their general health and the condition of their urine, either without treatment of any kind or in connection with treatment of one kind and another. Such improvement is not infrequently maintained for months at a time, in spite of the universally conceded fact that the tendency of chronic Bright's disease, whether its course be more or less protracted, is inevitably to a fatal issue. To prove that cure or improvement after renal decapsulation is due to the operation, it must be shown: First, that cure or improvement follows operation with practical uniformity; second, that a cure, once obtained, is, as a rule, lasting; third, that improvement attained by operation is steadily progressive in character in the great majority of cases. These conditions, as I hope to show, have been fulfilled in my cases as far as their limited number and the necessarily brief lapse of time since operation in most of them will permit of tenable deductions and conclusions.

The therapeutic results of renal decapsulation for chronic Bright's disease have turned out more or less unsatisfactory in only two of the twenty-four patients. The first of these cases really constitutes a relapse after cure. It is Case No. 5 of my original report of December 21, 1901. The patient, a married woman of forty-two, first learned that she had chronic Bright's disease in 1891, and for six years thereafter was under constant medical treatment for the affection. On April 1, 1897, I operated upon her right kidney, which was found to be the seat of chronic interstitial nephritis. During the year following operation steady improvement of the general health kept pace with the gradual disappearance of albumin and casts from the urine. A year after operation the urine finally became free from albumin and casts, and so remained, as evidenced by frequently repeated examinations, for nearly four years, during which she considered herself perfectly well. In February, 1902, four years and ten months after operation, albumin and casts reappeared in the urine, and have been found on every urinalysis made during the past year. She again has chronic nephritis, though she does not as yet feel ill enough to take the necessary steps to ascertain whether both kidneys are affected, or, if one only, whether the right kidney originally operated upon, or its fellow, be diseased. Catheterization of both ureters and examination of the separate urines of each kidney would, of course, determine that exceedingly interesting point, so pregnant with practical significance, which I still hope some day to settle.

The second patient in whom the results of decapsulation are not all that could be desired is a married woman of twenty-three, Case No. 14 of my previous report, with a very bad family history as regards chronic Bright's disease, of which her mother died at forty, and her only sister at twenty-seven. Her

father, still living, is also a sufferer from the affection. The patient was under constant treatment for chronic Bright's disease by her physician, Dr. Henry Ruhl, for more than a year prior to operation, which was performed on April 8, 1901. Both kidneys were found to be affected with chronic diffuse nephritis, and were decapsulated and anchored. For eight months after operation there was steady and satisfactory improvement, both as regards the general health and the findings on urinalysis. During the year past, however, she has suffered from an attack of diphtheria, two or three severe attacks of grippe, and an almost uninterrupted succession of colds. Exacerbations of her chronic nephritis were invariable accompaniments of all these infections, and she has made no gain, as far as the urinalysis findings go, over her condition of a year ago.

Of the remaining twenty-two patients ten were radically cured of their former chronic Bright's disease, and twelve were greatly improved. A number of the twelve, in addition, appear to be on the high road to a complete and perfect cure. One of the cured cases has already been reported among the deaths, the patient dying after an operation for ruptured tubal pregnancy, one year after my operation on her kidneys. Nine patients remain cured and in the enjoyment of perfect health, with urine free from albumin and casts, at periods varying from one year and nine months to ten years after operation. From the nine cured patients, as well as from ten of those improved, I have received reports, either written or personally presented, together with a specimen of urine for examination, during the month of January, 1903. Of the remaining two, one, a physician, informed me in November, 1902, that his urine was steadily improving, and writes me in January, 1903, that he continues doing well. The other patient, I am informed, is doing well, but I cannot locate him, as he is at present girdling the globe as a traveller.

A study of the phenomena accompanying and demonstrating the progress through improvement to cure after decapsulation of the kidneys for chronic Bright's disease, is exceedingly interesting. The first effect of the operation upon the urine is shown in an increased daily output of urea. I have known a daily excretion of six grams or less of urea, prior to operation, to be increased to a steady daily output of thirty to thirty-five grams within a month after operation. While the greatest relative gain in the urea output is generally manifested during the first two or three months after operation, the tendency later, although slower in progress and with transient disturbances, is steadily in the direction of a normal daily amount. Of the casts present before operation, those varieties like the waxy, fatty, epithelial, and pus casts, which denote advanced destruction of the secreting structure of the kidney, disappear first from the urine, such disappearance usually requiring from a month to over a year. The next step in the progress toward health is denoted by finding in the urine only granular and hyaline casts and albumin. The granular and hyaline casts gradually become fewer and fewer, and finally disappear entirely. The albumin, in gradually diminishing amounts, usually persists in the urine for a greater or less time after the permanent disappearance of all casts. Occasionally the patient passes through a brief period of typical cyclic albuminuria before the health of the kidneys is finally re-established.

Coincident and progressively with this improvement in the condition of the urine, the patient's general health improves in other respects. Strength returns to the muscles, and color to the face. The backaches, headaches, and digestive disturbances grow less and less and finally disappear. Unless the cardiac and vascular degenerations have progressed beyond a stage at which a restoration to health or comparative health is still possible, the dyspnœa and circulatory disorders accompanying chronic Bright's disease also improve in varying degree.

Such is a general outline of the progress of patients after operation in the favorable cases. Among my patients were eight physicians, upon each of whom I performed bilateral renal decapsulation for chronic Bright's disease. Three of them (Cases Nos. 35, 36, 39) are dead, while two others have only recently been operated upon. The remaining three have favored me with letters regarding their condition since operation, and have kindly given me permission to publish them. None of the three has as yet recovered health; they are merely booked as improved. Their experience, however, so well illustrates the progress of the other patients who are still improving after operation, without having as yet attained a cure, that I cannot refrain from citing them.

Case 20.—Male, physician, twenty-six years of age. Family history as regards liability to kidney affections very bad, five members of his immediate family having died of renal hemorrhage. Five attacks of grippe between 1896 and 1900. Severe hæmaturia for three days during last attack and some blood in the urine ever since. Chronic Bright's disease was first recognized in July, 1900. Decapsulation of both kidneys for bilateral chronic parenchymatous nephritis was performed on January 27, 1902. The last time I saw the patient was in November, 1902, when he was suffering from a severe cold accompanied by hæmaturia and an exacerbation of his chronic nephritis. Under date of January 24, 1903, the doctor writes: "Comparing my condition of health during the twelve months prior to my operation in January, 1902, with that of the twelve months succeeding, I feel greatly encouraged, and am confident that whereas there was a progressive though gradual decline in health before operation, there has been even a more marked, yet also a very gradual, improvement since. At times the course of improvement has been interrupted by acute outbreaks, which in every case were the result of colds; but the general tendency toward what has seemed complete recovery has not been altered. At the present writing I consider myself far from well, yet I must admit that to all appearances I am a stronger, healthier man than when I first discovered the existence of my nephritis two and a half years ago."

Case 22.—Male, physician, aged thirty-six years. Father died of chronic Bright's disease. Patient has had chronic Bright's disease for three years past. On March 26, 1902, I performed bilateral renal decapsulation for right and left chronic diffuse nephritis. Under date of January 19, 1903, the doctor writes: "Since my operation I have taken no drugs of any kind, have not restricted my diet in any way, and have attended to a general practice without missing a day. This is the first winter in three years that I have not suffered from cold hands and feet. In 1901 and 1902 my hands were so cold that my patients would complain of them when I found it necessary to make an examination of any kind. I am now entirely free from all head symptoms, whereas formerly I suffered intensely from headaches. The pain in the back peculiar to those suffering from Bright's disease has ceased entirely. Formerly I suffered with pain in the calves of the legs, but never feel it now. In 1901 and 1902 I suffered from palpitation of the heart which would

wake me at night; never have it now. My pulse formerly full and bounding, is now much improved. I have lost that feeling of lassitude and weakness, and can now work all day, where formerly I would get tired in a few hours. That peculiar powdery condition of the skin of the hands has almost entirely gone. I receive constant unsolicited evidence of my improved health from the remarks of my patients commenting on my improved appearance now as compared with formerly."

Case 37.—Male, physician, fifty-one years of age. An attack of diphtheria in 1876 was followed by general paralysis lasting five months. After that his health was never good. In 1885 his eyesight failed, and retinitis albuminurica and chronic Bright's disease were diagnosticated. A varying amount of œdema, uræmic headaches, backaches, and attacks of gout have been the symptoms for seventeen years past. In 1886 the doctor retired from professional work and sought recuperation for three and a half years in a mild climate in the middle West. Finding that the climate did him more good than anything else, the doctor resolved to spend his life in that locality, and established a sanitarium chiefly for the reception and treatment of cases of chronic Bright's disease. There he remained for twelve years, taking care of himself and his patients, until he heard of renal decapsulation for chronic Bright's disease, when he hastened to New York and asked me to operate upon his kidneys. The operation was performed on June 2, 1902, and disclosed bilateral chronic diffuse nephritis. Under date of January 19, 1903, the doctor writes: "I can only state that the operation did me a whole lot of good. I was operated upon June 2, 1902, and on July 12 I went to work again. I gradually gained strength and flesh, my color improved, and the uræmic headaches disappeared. By September the general dropsy had entirely disappeared; but for the past two months there has been some reaccumulation of fluid in the abdomen, and I am suffering from digestive disturbances. I sometimes fear that I have some liver complication. I am at work, however, and feel better than I have at any time for the past five years."

I may add that the urine of each of the three medical patients quoted has shown a steady tendency, in spite of occasional setbacks and interruptions, to return to a normal standard.

Of about the same tenor as the above are the reports from the other patients who are registered as improving. Of the twelve patients thus classed the urine of one is at present free from albumin and casts, one has reached the stage of cyclic albuminuria without casts, two have a trace of albumin without casts, while in eight, favorable changes in the condition of the urine exist, but are less marked. All the patients but one report improved general health as going with the improvement in the renal secretion. The one exceptional patient suffers much from headache and digestive disturbances, although the condition of the urine is steadily improving.

We come finally to the cures of chronic Bright's disease after renal decapsulation, which number nine survivors and one patient, Case No. 11, who died an accidental death after being cured of her former kidney affection. To be classed as a cure the following conditions must be fulfilled in a given case: The urine must remain free from albumin and casts, and the daily urea output be normal, or approximately so, for a period of at least six months following the verification of the disappearance of albumin and casts, and the patient must be free from the symptoms of chronic Bright's disease from which he or she formerly suffered. All of the nine cases listed in the table have fully met the above requirements. The patient who died an accidental death after being cured of chronic Bright's disease, and the patient who was cured of chronic Bright's disease, remained cured for four years, and is at present suffering from a relapse, are not included in the list.

Nine patients, therefore, remain cured at periods of time varying from one year and nine months to over ten years after operation, the duration of cure for the nine cases averaging a little over four and one-third years. Eight of the cured patients had chronic interstitial nephritis; one had chronic diffuse nephritis. It is true that these earlier cases, as a rule, represented milder types of chronic Bright's

TABLE OF AUTHOR'S CASES OF CHRONIC BRIGHT'S DISEASE CURED BY OPERATION.

Case No.	Known Existence of Chronic Bright's Disease Prior to Operation.	Date of Operation.	Variety of Chronic Bright's Disease	Time from Operation to final and permanent disappearance of albumin and casts from urine.	Date of Last examination of urine	Period of Observation from operation to last examination of urine.	Duration of Cure
1	1 year	20—XI–1892 Right kidney.	Chronic interstitial nephritis.	2 months.	4–II–1903	10 years and 2 months.	10 years.
4	?	11–I–1896 Both kidneys.	Chronic interstitial nephritis.	4 months.	18–I–1903	7 years.	6 years and 8 months.
6	?	10–I–1898 Both kidneys.	Chronic interstitial nephritis.	1 month.	21–I–1903	5 years.	4 years and 11 months.
7	2 months	14–I–1899 Both kidneys	Chronic interstitial nephritis.	5 months.	22–I–1903	4 years.	3 years and 7 months.
8	?	6–III–1899 Both kidneys.	Chronic interstitial nephritis.	4 months.	20–I–1903	3 years and 10 months.	3 years and 6 months.
12	?	5–XI–1899 Both kidneys.	Chronic interstitial nephritis	2 months.	4–II–1903	3 years and 3 months.	3 years and 1 month.
13	?	30–XI–1900 Right kidney. 19–IV–1901 Left kidney.	Chronic interstitial nephritis.	5 months.	23–I–1903	1 year and 9 months.	1 year and 4 months.
15	1 year and 6 months.	15–IV–1901 Both kidneys.	Chronic interstitial nephritis.	7 months.	4–II–1903	1 year and 9 months.	1 year and 2 months.
16	1 month.	6–V–1901 Both kidneys.	Chronic diffuse nephritis.	7 months.	20–I–1903	1 year and 9 months.	1 year and 2 months.

disease than those operated upon in 1902. Yet the progress being made by the latter toward health is essentially the same in character and kind, although corresponding to the longer period of existence of the disease, slower than that of the earlier cases. It must be recalled that the 1902 series were all inveterate cases of severe, complicated and far advanced chronic Bright's disease, a series the equal of which in total average severity may not, perhaps, be encountered in any year to come. Taking this fact into account, the showing made in the sum total of improvement presented by the surviving patients of 1902 must be considered as remarkably gratifying and encouraging. It gives rise to the hope that a number of them may figure in the list of cures of my next report.

There remain for brief mention eleven patients operated upon during the latter half of 1902. The death of one of these, Case No. 47, has already been detailed. Of the remaining ten all but one are, at the present writing, progressing satisfactorily. The time elapsed since operation is, however, too short to speak of final results.

The great majority of my patients returned to their usual vocations within two months after operation. Among those who thus resumed their places in life were quite a number who had either been bedridden or invalided to the extent of being disabled for work for months, and, in a few instances, for years prior to operation. As a rule the ordinary restrictions of diet usually imposed upon sufferers from chronic Bright's disease were cast off by my patients after operation, and but a minority of them received any further medical treatment. I have always, however, urged upon them the desirability of placing themselves under the constant professional care and supervision of their family physician, whose coöperation with the surgeon I am convinced is necessary to secure the best results.

The general practitioner, on the other hand, in the present state of our knowledge, owes it to himself and to his patient to accord practical recognition to two important facts. The first of these facts is that chronic Bright's disease, at least in its earlier stages, before irreparable and fatal damage has been inflicted upon the kidneys, the heart, the blood vessels and the nervous system, is curable or susceptible of amelioration by renal decapsulation. The second fact is that renal decapsulation in the *early* stages of chronic Bright's disease is, in competent hands, attended with little or no risk to life. The practical application of these facts is self-evident.

This paper is presented as a report of progress, and, taken in conjunction with the writer's previous publications on the same subject, is believed to fairly reflect the actual present status of our knowledge of the treatment of chronic Bright's disease by renal decapsulation. It was my original purpose to present in tabular form full details of each of the fifty-one cases in which I have operated upon kidneys the seat of chronic Bright's disease. Such a course, however, would have unduly lengthened a communication already too long, and would, in addition, have served no useful purpose, inasmuch as all deductions of practical value which can be legitimately drawn at the present time have been sufficiently set forth in the text. Possibly such a detailed tabulation may, for one reason or another, prove desirable in a future report dealing with a larger number of cases and longer periods of observation.

In conclusion permit me to present the following:

Summary of results of renal decapsulation for chronic Bright's disease in author's fifty-one cases, embracing forty-seven operations upon both kidneys and four operations on one kidney only:

Seven patients died within seventeen days after operation.

Seven patients died at periods after operation varying between two months and eight years, the average period of life after operation being one year and eight months.

Two patients do not show improvement satisfactory in every respect.

Twenty-two patients are in various stages of satisfactory improvement and progress toward health at periods varying between two months and fifteen months after operation. The urine of several of these is at present free from albumin and casts. They have not, however, passed the probationary period of six months of normal urine, before the expiration of which no patient is entitled to a place on the list of cures.

One patient, after a cure extending over a period of four years, again has chronic Bright's disease. One of her kidneys only was operated upon.

Nine patients were cured of chronic Bright's disease and remain cured at periods after operation varying from one year and nine months to ten years, the average duration of cure being over four years. For details see table.

Three patients disappeared from observation after leaving hospital, and no trace of them can be found.

LITERATURE.

The appended literature includes such articles on the subject of the surgical treatment of nephritis, both acute and chronic, as have come to my knowledge, and which have not already been cited in the literature references accompanying my previous publications. A number of contributions dealing merely with theoretical considerations, and of little or no practical aid in the solution of the problem of the surgical treatment of chronic Bright's disease, have been omitted from the list.

SPECIFIC TREATMENT OF DIPHTHERIA.*

By GEORGE B. PHILHOWER, M.D.,
NUTLEY, N. J.

That great Norwegian, Alfred Bernhard Nobel, the discoverer of dynamite, feeling that he had incurred a great debt to society by introducing a chemical that would prove to become dangerous and destructive to man, willed that the income from his estate should go as prizes to those "Who shall have contributed most to benefit mankind during the year immediately preceding. One portion or share to chemistry, one to physics, one to medicine, one to literature, and one to the person having done most to increase the fraternity of nations." Thus did this renowned scientist hope, in a degree, to offset his obligations to mankind by encouraging original research and investigation along lines that would produce something to add to the comfort and length of human life.

The committee having charge of the awarding of the Nobel prizes decreed on the tenth day of December, 1901, at the Caroline Medical Institute, in Stockholm, that to Professor Behring should go the signal honor of having won the prize in medicine, and also some forty-one thousand six hundred dollars in money, as a reward for his discovery of antidiphtheritic serum. While those of us who have employed this life-saving serum to some extent are gratified that upon Behring was conferred the enviable distinction of receiving one of the Nobel prizes, we also conclude from our results obtained by the use of his remedy that Nobel's debt to society would have been cancelled in full had his entire fortune gone to Behring.

Nothing in our therapeutics equals it as a curative agent against this once dread disease, diphtheria. One of the leading surgeons of your city, in a conversation with me a few weeks ago, said: "No operation in surgery compares with it in saving life or in alleviating suffering." It would seem to admit of no further argument that it easily ranks as the second greatest life-saving remedy of the nineteenth century.

To come before your Society, in the face of almost universally favorable reports in the treatment of diphtheria by the use of antitoxin, with a paper upon this subject is like "adding perfume to the violet," or "painting the lily," and should demand some excuse, therefore, from the writer.

In a neighboring town, the president of the health board, a physician, does not advocate the use of antitoxin in diphtheria, stating as his reason for this advanced opinion, that: "The high temperature should not be controlled, as it burns up the bacilli, and is of much help to the patient on his road to recovery. Another physician of my acquaintance sat beside his little son for three weeks, and constantly removed bits of membrane from his boy's throat that he might give to the little sufferer some relief to his obstructed breathing. When asked if he employed antitoxin replied: "I did not think antitoxin was indicated in my boy's case."

There come to my office, at frequent intervals, sample copies of a medical journal which has printed across the title-page in large letters this interesting announcement: "The largest circulation of any medical journal in the world." Judging from the reasonable cost with which it comes to the reader, from the large number of contributors, who write from every State in the country, and from the fact that the editor signs his name A.M., M.D., the conspicuous statement must be correct. A few months ago the editor of this very largely circulated journal wrote above his own signature: "That whatever of curative value antitoxin possessed was not due to the serum of an immunized horse, but to the antiseptic in which the serum is preserved." He closes his absurd article by stating that: "A solution of carbolic acid of the same strength would do just as well." On page 1322, September, 1902, of this same journal, I read these astonishing words: "Give it that dose of antitoxin you have in your chest, which is not less than six months old, and calmly sit down and wait for the deadly disease to get in its work. Remember that you are miles away from any place where fresh antitoxin can be secured, and there is no chance whatever of getting it. There is but one alternative. If you have pinned your whole faith to antitoxin, then you have nothing to do but give it and watch the little fellow die."

Bovaird and Northrup, in Sajou's *Annual*, say it can be kept one year in a fresh condition. The writer has found it pure and sweet after a period of eight months, and has then used the trial vial with excellent results. It is appalling to think of the immense amount of harm such writing in these far-reaching periodicals can do to the very men who, miles and miles away in the country, have in antitoxin a certain and specific weapon against that awful scourge diphtheria. The country physician who employs antitoxin skilfully and courageously in diphtheria will have a lower death-rate than can be obtained in the city, as the better sanitary conditions will help him very materially. Just as sure as yellow journalism in secular affairs gives rise to discontentment among a certain class of society, and excites it to riot and disorder, just so sure does cheap journalism in medicine keep some men from seeing the truth, and stands in the way of progress along scientific lines.

The writer feels it incumbent upon him to ask your Society to bear him out in pronouncing most emphatically against such frightfully misleading statements as come to us through these cheap medical journals. Have we a true specific in antitoxin, as we now employ it in diphtheria? Quain defines a specific as: "A substance having a specific and definite effect in the cure of disease, such as mercury in syphilis, or quinine in malaria." Drs. Bovaird and Northrup state that in only three years it had won for itself the right to be regarded as a specific. The present evidence is overwhelmingly in favor of its being a true specific in diphtheria, and it has now stood a most rigid test for eight years in both hospital and private practice.

It is not expedient that your patience should be taxed with many quotations to prove the foregoing statement, suffice it for me to refer you to an

*A paper read before the Practitioners' Club of the City of Newark, N. J.

exhaustive article in *Pediatrics*, July, 1902, by Adolph O. Pfingst, M.D., of Louisville, Ky., and from which I have culled the following interesting and instructive facts: Twelve of the largest cities in the world show an average mortality of 12.5 per cent. for a period of five years after the use of antitoxin, in six of these twelve cities a mortality of 33.48 per cent. obtained for five years previous to the introduction of Behring's serum; which means that more than twenty lives in every hundred were saved. J. C. Cook of Chicago reports one hundred cases with but one death. Many other private records show a death rate of only from 1 to 5 per cent.

From March, 1886, to November, 1895, a period of nearly ten years, eighty-six cases of diphtheria in my practice, treated with the most approved methods in vogue during those years, such as bichloride of mercury, tincture of the chloride of iron (recommended by Jacobi), sulphur, hydrogen-dioxide, calomel sublimations, etc., gave me the alarming number of twenty-seven dead children, a per cent. of 31. plus; in other words, every third child died. My results during those ten years were no worse than my neighboring physicians obtained; many of whom, in consultation with me, saw my patients and endorsed my care and treatment of them, but none could render any aid or assistance that would save more than two out of three of my patients. During the year 1888 some fifty cases were treated in our community with a mortality of 40 per cent.; thus I felt that my failures were not due to my early years and immature judgment alone, but that diphtheria was either the worst disease physicians were called upon to treat, or else they did not know how to treat it.

In taking a review of my cases before the introduction of antitoxin, and during the seven years since, it seems to me that, aside from whiskey and strychnine, as heart stimulants, iron for anæmia, and some relief in laryngeal cases from the burning of large powders of calomel on a stove-lid, nothing that I did appeared in any way to modify or control the ravages of the disease. In one family alone I spent an entire week, day and night, to be rewarded by having my three little patients die one after the other.

How eagerly, then, did I watch the results of those thoughtful, courageous men, who began to use antitoxin during its early history, and when it received the endorsement of a few men, whose opinions were greatly respected, I resolved to try it in my next case.

On November 17, 1895, I was called to visit Rudolph D., aged four years, who had been sick twenty-four hours with a high fever, sore throat, and persistent vomiting. His throat was filled with false membrane, which covered his tonsils and uvula, obstructed his breathing to such a marked degree that his efforts to fill his lungs could be heard from below stairs, his temperature was 103° F., pulse 120 per minute, and respiration 40 per minute, and distinctly croupy. This particular group of symptoms led to the diagnosis of tonsillar diphtheria, with probably some involvement of the larynx, or, at least, with a tendency to extend downward into the larynx, thus making the prognosis grave.

Obtaining the consent of his parents, 1,000 units of antitoxin (a dose which we now know was entirely too small) was injected into his thigh. The child being no better, but rather worse, in twelve hours, the same amount of serum was repeated, and no other treatment of a specific nature given. Whiskey and strychnine being the only other therapeutics employed, and those only on general principles. The second injection arrested the growth of the membrane inside of twelve hours. In twenty-four hours the edges loosened and began to curl up. In twenty-four hours more his throat was free from membrane, and he was declared to be clinically well, so far as danger of choking was concerned, although he was kept in bed for two weeks.

This lengthy detailed description of my first case is given because it was symbolic of my treatment, as based upon the course of clinical evidence, in all of my other cases, and shows characteristically what antitoxin will do in these desperate cases.

Just one week later, November 25, 1895, my second patient, Mrs. G., a delicate young woman, who had been sick two days with what appeared to be a mild attack of diphtheria, was injected with 1,000 units. Forty-eight hours after receiving the antitoxin, her throat was quite free from membrane, but she turned blue at her lips and finger-tips, and, in spite of large doses of whiskey and strychnine, she died on the fourth day of her disease. This sad result was disappointing to me, but not discouraging, as I could not reason that the antitoxin was in any way responsible for her cardiac paralysis.

There were no more deaths until my twenty-sixth case was reached: a little girl two years old, sick with diphtheria four days, and in coma when I first saw her. Six thousand units in all, given in 1,000 unit doses, every twelve hours, brought her back to consciousness, lowered her temperature to normal, when she took food with avidity, and spent her days playing with her toys. This baby died, however, twelve days after her first injection, and after having had a normal temperature for four days, with some chest trouble, which was diagnosed bronchopneumonia.

My third and last case in my series of one hundred was number eighty-six, and as far as possible to determine, antitoxin failed absolutely to control, or check in any way, the fatal course of her disease. Our patient was a well-developed and well-nourished little girl, aged eight years, whom I visited a few hours after she took to her bed with headache, fever, vomiting, and marked swelling of the glands at the angle of her jaw; she did not complain of sore throat, nor did her throat upon inspection show anything more than enlarged tonsils, which were somewhat reddened and covered with a great deal of stringy, ropy, offensive mucus; her breath was intensely offensive, somehow reminding me of diphtheria.

This peculiarly offensive breath is of marked diagnostic value, and antitoxin is frequently given in my practice because of this symptom alone, and when there is no visible membrane. Inasmuch as it seemed so likely to be diphtheria, my second visit was made six hours later, when a suspicious patch, as large as a ten-cent-piece, upon her right tonsil led me to give her 2,000 units of antitoxin. The patch grew, and another appeared upon her left tonsil, when 2,000 units more were given with no apparent benefit, for soon after croupy symptoms came on, when 2,000 units more were given, and Dr. Corwin of your city was requested to intubate her. With no very alarming laryngeal symptoms, the tube was skilfully inserted on the second afternoon of her illness, and we decided to give her 2,000 units more, making 8,000 units in all, after which there were no further untoward symptoms for twelve hours, when she became cyanotic, and breathed with great difficulty. Dr. Corwin hurried to us and removed the tube, hoping that a bit of membrane might be occluding it. That not proving to be the cause of her distressed breathing, she ceased to breathe a few hours after its reinsertion.

This patient was one of a group of ten, and the

type of disease that afflicted them was very severe, necessitating larger doses of antitoxin than I had ever used, before the disease was checked. To four of the children were given 8,000 units, in two doses of 4,000 units each, and then the membrane ceased to grow.

Dr. Taylor of Asbury Park treated two children of this same group, and found it necessary to give larger doses than usual. Loomis in his day taught that all epidemic diseases varied greatly in regard to their virulence. Sydenham, who had an extensive practice among children, went twenty-seven years without seeing a single death from scarlet fever, and then brought himself within the range of criticism by stating that physicians did not know how to treat scarlet fever. The twenty-eighth year nearly all of his scarlet-fever patients died. It behooves us, therefore, to be ever on the look-out for these severe epidemics of diphtheria, and control the disease with extremely large doses of antitoxin; for severe cases are just as surely controllable with large doses as are mild cases with small doses, if given early in the disease.

The best writers on the treatment of diphtheria by the use of antitoxin plead for much larger doses than we have been in the habit of giving. J. H. McCollom (*Providence Medical Journal*, July, 1902) says: "Since larger doses of antitoxin have been given, the death rate has been materially reduced, this reduction having occurred in the apparently moribund cases;" he further states: "No injurious effect has followed the use of the serum." Dr. McCollom's statements are based upon results obtained in the Boston City Hospital.

One writer from Boston advises as much as 30,000 to 40,000 units in bad cases, claiming that not a few children are saved by these colossal doses, who would die if less heroic measures were employed. In my one apparently uncontrollable case, I believe an initial dose of 4,000 or 6,000 units would have undoubtedly arrested the disease, but I had no clinical evidence of its being anything more than an ordinary case of diphtheritic poisoning.

If it were possible to estimate the amount of diphtheritic poison at work in every case by the clinical evidence, our mortality would be nil, as an equivalent dose of serum in the early stages would neutralize the infection. Let me illustrate the above statement: One grain of morphine gives rise to the same physical symptoms as two grains would cause, and to give only one grain of permanganate of potash would probably not save the patient if he had taken two grains of morphine, whereas if he had taken but one grain of morphine and two grains of permanganate were given, it would be substituting one poison for another. This statement will probably bring a nest of hornets about my head, as so many investigators claim that antitoxin is not a neutralizer of the toxins of diphtheria, but merely increase the resisting powers of the body against any further invasion of the toxins of the disease.

It is not meet and proper to inflict you at this time with the various theories as to the action of antitoxin upon the human system, but permit me to state, that for all practical purposes, it is much safer to employ and deal with antitoxin only in the nature of an antidotal chemical poison. The very name given to it by its discoverer means opposed to the toxins of diphtheria, hence if there be a large amount of diphtheritic toxæmia at work it will require correspondingly large doses of serum to neutralize it.

The action of antitoxin upon diphtheritic membrane, being specific and definite, we must obtain definite and specific results. The growth of the membrane must be arrested in the first twenty-four hours, its edges should be caused to loosen and turn up during the second twenty-four, and it must be caused to crumble and come away in the third twenty-four, else our dose is not large enough or strong enough.

The earlier it is given in all cases the better the results, but never refuse to give it in any case however late. The most marked effect that I witnessed was on the comatose child, which was injected on the fourth day of the disease and lived twelve days thereafter.

As to the method of giving: Tonsillar cases do well invariably with 2,000 units, 10 c.c. in quantity. Nasal cases require from 4,000 to 6,000 units, laryngeal cases should receive from 6,000 to 10,000 units. Diphtheria characterized by a great amount of glandular swelling should be given very large doses, from 4,000 to 6,000 units, for the swelling indicates an extensive poisoning. Pfingst speaks in the highest terms of large doses of antitoxin in laryngeal involvement. Dr. Samuel G. Dabney of Louisville, Ky., reports a case of a child in extremis cured by intubation, strychnine, and antitoxin.

It was both unique and interesting that my one hundredth case was a desperate laryngeal one of three days' run. The child was croupy, voiceless, wet, and blue when Dr. Corwin intubated him, and he was given 8,000 units of serum, 2,000 units every twelve hours, until he recovered; of course in his case strychnine supplemented the serum. We can but conclude from these moribund laryngeal cases, that recover since the use of antitoxin, that we have in it a true specific of the most marked value, for they did not get well under any other treatment.

It has been claimed by the skeptics that we have been having a mild type of diphtheria during these seven years, and the death rate would have been low under any form of treatment. My reply to that assertion is that for a period of ten years a mortality of 31 per cent. obtained without antitoxin, and during a run of seven years only 3 per cent. of my patients died under the antitoxin treatment. Can we by any possible process reason that the difference in the type of the disease during all of these years has made this marked reduction in mortality? In the year 1898 four cases treated in my town without antitoxin gave two deaths, thus going straight back to the old high mortality of 50 per cent.

Eighteen cases treated at the same time, two of which were in families in which the deaths occurred, all recovered under the use of antitoxin. These eighteen cases were treated by four different physicians.

Again we are met with the astonishing argument that we are not dealing with true diphtheria. What then is this disease whose grouped symptoms we usually pronounce diphtheria, which for ten years killed every third child in my practice, which kept me with my patients constantly until they either recovered or died? Cultures taken from about 80 per cent. of these one hundred cases showed the presence of the Klebs-Loefler bacilli. The results of the cultures (many of them) are on record at our State Laboratory at Princeton.

In conclusion let me state that since 1895 antitoxin has saved twenty-eight children for me, has given to me just about one year's more sleep than I could have enjoyed without its use; an item of no small moment to a fatigued physician. It has saved hundreds of dollars to my patients, my visits averaging six per patient, whereas before it required

an average of fourteen per patient. Many of our patients being poor, we should employ such means as will cure them quickly.

I feel so seriously about the non-employment of antitoxin in diphtheria, that, if possible, I should have laws passed making its use obligatory to every person treating diphtheria, and would prosecute every physician for malpractice who treats a fatal case without its use. I hold that any man who is so bigoted as not to employ faithfully and skilfully any remedy that saves from twenty to thirty patients per hundred, and which is absolutely free from any deleterious effect upon the human system, which has stood the most rigid trial for eight years, and which receives the endorsement of the most careful, competent men, is not treating his cases with ordinary skill, as is required by the laws of our State.

As to the kinds of serum to employ, my experience would lead me to recommend a 2,000 unit strength, to the 10 c.c. in quantity. It is best to accustom ourselves to one reliable manufacture and stick to it, as we will administer it more heroically and confidently.

THE PSYCHICAL ELEMENT IN HAY-FEVER.

By RAYMOND WALLACE, M.S., M.D.,
CHATTANOOGA, TENN.

Much has been written during the past few years upon the subject of hay-fever, and although very little new as to etiology has developed, the number of articles may be justified as a sincere attempt to fathom the etiology and to discover more specific methods of treatment. The present brief article, with its somewhat detailed observation of four cases from the standpoint of the psychical factor, may, perhaps, be pardoned on the same grounds.

It is now quite generally agreed that the etiology of this disease may be broadly summarized under three heads—a more or less disordered nervous system, an irritable nasal mucosa, and a stimulus. It is undoubtedly true that persons, naturally high-strung, excitable, irritable, neurasthenic, having nerves which are literally on the surface, are more liable to this affection than are the more phlegmatic types. Yet the second factor may be so prominent in this latter type that it, of itself, may give rise to paroxysms. The second and third factors have been so often discussed that they need not concern us here—except the inter-relationship of the three, acting as causative factors.

The element of periodicity in attacks first emphasized to me the presence of a potent psychical element in certain cases, which is a considerable factor in the precipitation of attacks. Periodicity cannot always be explained on physical grounds. For instance, it is a recognized fact that while a victim of hay-fever may live perfectly immune up to a certain date—with scarcely a premonitory symptom, and then, knowing from past experience that at just noon of the 15th of August the last year's attack began, within an hour's time the vasomotor paralysis may begin, and in less than three hours a first-class attack be thoroughly initiated.

Then again, a patient, a neurotic young woman, age twenty-five, seldom has more than three attacks a day, and during the interval she is comparatively free from distressing symptoms. Upon arising from bed in the morning she always anticipates, from past experience, an attack, and it always comes, unless, occasionally, by pressing the nostrils together forcibly, or by making firm pressure upon the upper lip, she may abort it. Again, at the lunch hour, an attack is always expected, and the expectation is generally fulfilled. Lastly, she may be almost entirely without symptoms, and, upon entering her room for the night, sneezing would begin, and the usual last periodic attack of the day would be in full force.

Again, a young man, age thirty, has had hay-fever for four years. He is predisposed by a neurotic constitution, a hypertrophic rhinitis, a granular conjunctivitis, and some bronchial irritation. Yet the element of periodicity is here very strong. With medication, he controls the attacks, so that he has only four or five during the day. But should he be in conversation with a person, upon whom, for instance, he desired to make a favorable impression—the thought of his hay-fever would initiate irritation, and an attack would be almost immediately precipitated. Again, if he be in society—his mind dwelling upon the possibility of an attack and its embarrassment—he will frequently have two or three during an evening and be compelled to leave the room. While on the other hand, if this same man work at his desk in the office for an entire evening—with his mind upon other things—he seldom is troubled by a single attack.

In another case, a woman, aged sixty-one, of very neurotic temperament, has had hay-fever for eleven years—and for several weeks preceding the month of August—her whole system seems to be struggling with the disease. She has attacks of morning nausea and vomiting, anorexia, a feeling of considerable prostration, a fulness in the head, and at times a dull headache. Her bowels become irregular—the nasal mucous membrane becomes gradually engorged—the eyes suffused—a sense of oppression is felt in the chest, and more or less dyspnœa follows. All these symptoms become more pronounced until the well-defined disease with continually repeated attacks is upon her.

This case is mentioned as an illustration of an almost complete absence of the psychical element. It is evident, then, that this factor does not possess the same relative importance in every case—but in certain cases I believe it to be an important, well-defined, and independent factor.

The question of priority in such cases may be argued,—whether the thought action comes first and is followed by the reflex vasomotor spasm, or whether the external stimulus acts, and instantaneously the sensation is conveyed to the psychical areas and the resulting impression is that the attack is of psychical origin. There is reason in this—but from the pathology of the disease—which is a disturbed equilibrium of the entire nervous mechanism,—a vasomotor neurosis, it is reasonable to suppose that the irritation, which may be either direct or reflex—may be a psychical irritation, coming to these areas through the various sensory channels—as well as mechanical irritation by dust, pollen, odors, etc. We know that direct sunlight entering the eyes often precipitates an attack. Here the reflex is through the optic tract. Why, then, may not impulses or irritations originating in the psychical areas reflexly excite the vasomotor spasm or paresis, and thus precipitate an attack.

The psychical element is a factor of growing importance in many disease processes, but seldom does it, as an excitant of reflex disturbances, play such a well-defined and recognizable part as in this particular malady. Further observations and experiments along this line will surely yield some most interesting and valuable results.

ON THE BIOLOGICAL RELATIONSHIP OF PROTEIDS AND ON PROTEID ASSIMILATION.

By P. A. LEVENE, M.D.,
NEW YORK.
FROM THE DEPARTMENT OF PHYSIOLOGICAL CHEMISTRY, PATHOLOGICAL INSTITUTE OF THE NEW YORK STATE HOSPITALS.

The works of Tschistowich, Bordet, Uhlenhuth, Wassersman, and especially the work of Myers, establish that when a proteid of foreign origin is injected into an animal, it acts in a way like a toxic substance. Thus, if a rabbit receives subcutaneously, intravenously, or intraperitoneally, injections of the proteids of the egg of fowl, it develops protective substances against them. The protective substance is called precipitin. The presence of the latter is demonstrated by the power of the blood serum of the treated animal to form precipitins, if allowed to remain in contact with a solution of the proteid used for the injections. Thus, the serum of a rabbit injected with casein is capable of forming precipitins with a solution of casein.

The first observers of this phenomenon considered the precipitins as having very specific properties, and a serum capable of precipitating a casein, as having no power to form precipitins with a solution of any other proteid. However, my own investigation into this subject lead me to the belief that the specificity of the precipitins is not so absolute. A short communication on this subject appeared last year in the *Medical News*, and the full work is to appear in the *Journal of Experimental Medicine*.

My observation was, that if the serum of an animal acquired the power to form precipitins with one proteid of an animal of a different species, it had the power to form precipitins also with other proteids of the same animal or of animals closely related to it.

Later Levoisser, Lemoine, and Camus came to the same view on the specificity of precipitins. The conclusion to be drawn from this observation is the following: Proteids have not only a chemical individuality, but also a biological one. Thus, chemically, all serum albumins are identical, biologically they are different. From the latter standpoint they may be regarded as isomers. Chemically different albumin, globulin, casein, etc., derived from the same animal may be regarded as having at least one part common to all of them, or, perhaps, may be regarded as derivatives of one substance, which is the nucleus of all the proteid-material of that animal.

Another observation I have made, and which corroborates the latter hypothesis, is that a precipitin active for a given proteid is capable of forming precipitins with the primary digestive products of the latter and *vice versa*.

This property of an organism to form precipitins against proteids that reach in one way or another its general circulation could be applied, it seemed to me, to the study of one of the most obscure problems of animal physiology, namely, to the question of proteid assimilation.

Where are the foreign proteids that are introduced into the digestive tract assimilated into the body proteids? Is this done within the digestive organs (liver included) or in other organs? Why should the proteids of the food be digested at all, and not simply absorbed, and thus utilized by the organism: or, in other words, why should they be decomposed before they are assimilated?

The biological distinction of proteids of different origin easily answers the latter question. The molecules of the foreign proteids have to be reconstructed. The question of the place of this reconstruction could be solved only experimentally. Several years ago I thought of solving the problem by feeding animals on iodoproteid, and then of searching for it in the organs. The work, however, was interrupted. Lately, in the laboratory of Prof. Kossel, Szumowski approached the problem in a similar manner; he fed animals on a vegetable proteid, zein, and then endeavored to find the substance in the organs. This, however, is a very rough method of investigation, and it seemed to me that the problem could be solved in the following manner: If foreign proteids introduced into the digestive tract enter the general circulation as such then the blood serum of an animal should form a precipitin against the foreign proteids which are used as food by the animal. If they enter the circulation even as primary digestive products of the proteids, as proteoses or peptons, even then a precipitin against those proteids should be formed. Some observations in that direction were made by Uhlenhuth and Hamburger. A thorough investigation into this subject was undertaken some time ago by Dr. L. B. Stookey and myself. Our work is not yet completed, and will be published in full later. We feel, however, already justified in the conclusion that the foreign proteids do not enter as such the general circulation. It is not improbable, however, that in pathological conditions they pass the digestive organs unchanged.

This may happen in conditions like total atrophy of the glandular tissue of the gastrointestinal wall, or in grave disorders in the function of the liver. Observations in this direction are wanting.

The Loss of Mental Vision.—A. Giannelli and G. Toscani by this term mean the power to form images in the mind of persons and objects previously seen, but for the moment absent. They report four cases in illustration. The first a woman of forty-one years, of neurotic heredity, and subject to epilepsy, when in the hospital was unable to recall her husband's appearance; this troubled her greatly. She was able to recognize his picture, but, when it was taken away, she could not recall even such a detail as whether or not he had a beard. Her case went on to mania. The second case was a man of great cultivation, who, after business troubles, suddenly found that everything about him seemed new and strange. Nothing was familiar, and, in addition, he was totally unable to recall the appearance of his wife and children. He spoke French correctly, but was no longer able to think in that language, and found the French words only by translating from the German or the Spanish, which were the languages of his childhood. He complained that he had lost all his enthusiasm, and that his character was becoming cold and indifferent. The third case was a man of sixty-eight, a diabetic, who was in a condition of melancholia, and who completely lost the power of reproducing in his mind the appearance of the objects most familiar to him. The fourth case was a man of forty, affected in the same way. He had suffered from overwork.—*Il Policlinico*, February, 1903.

Diagnosis and Treatment of Gallstones.—W. E. B. Davis says that the experience of the Drs. Mayo of Rochester, Minn., who have operated on a large number of cases with obscure symptoms referred to the stomach, in which stones were found in the gall-bladder or a cholecystitis was present, would indicate that a very much larger percentage than is usually supposed gives rise to symptoms, yet they are not those heretofore attributed to gallstone disease. Hence more frequent operations for vague symptoms referred to the stomach should characterize the practice of surgeons in the future. The author gives the differential diagnosis of gallstones from a number of other diseases. In cases in which the gall-bladder is very much contracted and cannot be found, and the liver so enlarged and adhesions so extensive with cholemia, that it is not advisable to search for the gall-bladder and ducts, hepatotomy should be done for the relief of this condition. The author has devised a method of doing a bloodless hepatotomy by means of lead bars which prevent the ligatures from cutting the liver tissue. This does away with all bleeding during the operation, and should it become necessary to leave the bars on, they may be removed in from forty-eight to seventy-two hours, by drawing on them with silk ligatures, the small catgut having previously been absorbed. This method is applicable in controlling bleeding in all the solid viscera as well as the lungs.—*The Mobile Medical and Surgical Journal.*

Thermotaxis of the White Blood-corpuscles.—M. A. Mendelson concludes: (1) The white blood-corpuscles possess a thermotactic power, in consequence of which they strive, within certain limits, to approach the regions of higher temperature, *i.e.* they are positively thermotactic. (2) The positive thermotaxic appears in the white blood-corpuscles, though in a very feeble degree, already at a temperature of 20°–25° C.; it becomes stronger at 25°–35° and reaches its highest point between 36°–39°; the thermotactic optimum of the white blood-corpuscles is between 39° and 39.5° C. (3) At a temperature above 40° C. no thermotactic movements could be discovered in the white blood-corpuscles; occasionally only some feeble movements in the direction of the lower temperatures were observable, but these movements were so feeble and occurred within such insignificant oscillations of temperature that it would hardly be safe to conclude from these single facts as to the existence of a negative thermotactic power in the white blood-corpuscles. At any rate, the existence alone of the positive thermotaxis in the white blood-corpuscles shows the great importance of this property of the white blood-corpuscles in divers pathological processes where the most prominent feature is the local rise of temperature. It is very probable that the white blood-corpuscles rush to the seat of inflammation for their phagocytic purposes as a consequence of both the chemotactic and thermotactic reaction.—*Russkii Vrotch.*

A Case of Tumor of the Pituitary Body.—Thomas Philip Cowen reports the case of a man of twenty-eight years who had suffered much from hemicrania affecting the right side of the head particularly. In 1895 he presented no signs of bodily ill health, and his viscera were apparently normal. His vision was good. Early in the following year he began to complain of failing vision, and it was found that he had slight bi-temporal hemianopia. In 1898 he became very melancholy because of failing vision. He had at this time a slight but persistent headache, which at times became very severe, situated always in the forehead. In 1899 he was quite blind. The pupils were wide and inactive to all stimuli. There was slight but well-marked atrophy of both optic disks. In November, 1901, he began to get dull and stuporous, and suffered from severe vomiting; gradually sank into coma and died two days later. At the autopsy a large tumor of the pituitary body was found. It was the size of a hen's egg, had not invaded the surrounding structures, but had exercised considerable pressure both on the adjacent brain and nerves, and had practically incorporated in its capsule the surrounding nerves. The optic chiasma and tracts were much flattened, the optic nerves being much flattened and softened. The third and fourth nerves were softened and flattened, and could be traced over the tumor only with difficulty on account of their adhesion to its capsule. The tumor was a fibrosarcoma.—*The Medical Chronicle.*

The Treatment of Spina Bifida.—William V. Laws says that he has had no good results from the injection treatment of this affection, and considers the open operation the best form of treatment, and the most in accordance with the progress that has been made in the treatment of other herniæ. He adopts the technique first described by Nicholl of Glasgow, which he gives in detail. Two cases are reported. In one the operation did not avert a fatal result, but in the second, a child seven months old, the results were in every way satisfactory. The tumor was the size of the child's head, and the sac had become so attenuated that it looked as if it might rupture at any moment. An elliptical incision was made around the base of the tumor, and after dissecting up the integument a small trocar was introduced and the fluid slowly withdrawn. On opening the sac one nerve was found to be closely adherent to its posterior surface, which was carefully dissected off and placed over the opening in the spinal canal, it not being possible to replace it in the spinal canal entirely. The sac was transfixed and ligated low down with chromicized catgut and then covered in with fascia, muscle, and skin flaps, three rows of catgut sutures being used. Collodium dressing was applied, and the operative field was walled off from the anal region by attaching a piece of rubber dam with adhesive plaster just below the lower end of the wound.—*The Pennsylvania Medical Journal.*

Ring Bodies in Anæmic Blood.—Richard C. Cabot calls attention to certain bodies found in anæmic blood, consisting of a set of granulations arranged distinctly in a circle, with no others inside or outside the circle. With Wright's modification of Leishmann's stain this ring is stained not blue, but red. At one point in the ring is often seen a large dot reminding us a little of the nucleus of a malarial parasite. There are several groups and kinds of rings. The rings are not parasites of any kind; their occurrence in disease as diverse as lead poisoning, pernicious anæmia and leukæmia would seem to settle that point. That they have some connection with anæmia is equally clear, since in every case in which they have been found a marked anæmia has been present. That they do not represent merely accidental configurations of the ordinary granular strippling is shown by the fact that they are sometimes continuous and not resolvable into discrete granules, and because they sometimes occur in cells quite free from strippling. The author thinks that they may represent nuclear remains; that is, portions of the nucleus especially resistant to the action of whatever forces it is that destroy the nucleus and ultimately the cell itself. He does not know whether they have any practical significance, but describes them because it seems the safest rule in scientific work to describe everything new that we come across, whether we see any significance in it or not.—*The Journal of Medical Research.*

The Heart and Life Insurance.—J. C. Sullivan concludes that we may class as good risks all those whose pulse is regular and not above 84. One whose pulse is regular and not below 60. One with valvular defects with compensating hypertrophy. All those with valvular defects which have existed two years, when the lungs and liver are healthy and the applicant is not addicted to the tobacco habit, and avoids alcohol in any form.—*The Illinois Medical Journal.*

KOCH ON TYPHOID FEVER.

PROFESSOR KOCH, on November 28, 1902, delivered an address on typhoid fever, at the Kaiser Wilhelm's Academy, a summary of which was given in the British *Medical Journal*, February 28.

The belief has long been held that the typhoid bacillus retains its vitality for a considerable period outside the human host. Recently, however, some investigators have stated that such is not the case, and that it is only under exceptional cirumstances the germ of typhoid lives separate from the body of man. Dr. Sidney Martin, F.R.S., summarizes the results of his investigations with regard to soil and typhoid fever as follows: (1) In certain virgin soils the typhoid bacillus neither grows nor lives; (2) after cultivation these soils become capable, "when sterilized," of maintaining the typhoid bacillus for a limited time; (3) cultivated soils—that is to say, soils containing organic matter—"when sterilized," support the bacillus for a long period and the bacilli spread through the soil; (4) "unsterilized" cultivated soil—or, in plain language, ordinary garden soil—is inimical to the bacilli; the microorganism cannot be obtained from such soil after twelve days or so.

Koch admits that he once thought that the typhoid bacillus was capable of a saprophytic life, retaining its vitality for a long time in water, and when it reaches the soil, lodging and multiplying there for years, while keeping the power, if disturbed, of starting afresh a parasitic career in human hosts. The German scientist now says that he has been compelled to abandon these views, and is of the opinion that the period of vitality of the organisms is very limited in water. As to their duration of life in the soil, he thinks that, under the favoring conditions of a moist soil and a free admixture of excremented matter, typhoid bacilli may retain their vitality for a week or two, a month, or even a whole winter, but not for much longer periods. Professor Koch concludes that the typhoid bacillus, like the cholera vibrio, in the soil, must be regarded as an obligatory parasite and dealt with accordingly.

With regard to the diagnosis of typhoid fever, Professor Koch holds the Widal reaction to be an inadequate test. He does not favor the plan of bacteriological culture, following the principle of using a medium which delays the growth of the typhoid organisms, until after the colonies of bacillus coli communis—which it is most important to separate—have attained a vigorous growth. He, after careful research, has become convinced that the method recently initiated by Drigalski and Conrad is the most effective, because, instead of retarding the development of typhoid colonies, these bacteriologists have made it their object to accelerate their growth, and have devised a culture medium which has a restraining effect upon the larger number of intestinal bacteria, other than those belonging to the coli group. Other organisms which may have succeeded in growing can be readily excluded by obvious differences in the appearance of their colonies, and it then remains to distinguish between the typhoid and coli organisms. Finally the presence of typhoid colonies is confirmed, and their possible confusion with other intestinal bacilli excluded, by the serum agglutination test. The writer asserts that by this method an absolutely reliable diagnosis can be made in twenty-four hours and the presence of typhoid organisms in patients recognized as early as the second day of the disease.

Professor Koch then describes at some length the successful practical application of these methods in a small epidemic of typhoid fever which occurred at Trier, Germany, and further states that all the cases witnessed there proceeded from direct infection from person to person, and were not in any way due to water pollution, although a brook was in close proximity to the cottages in which the disease was present.

Professor Koch seems inclined to somewhat depreciate the importance of cleanliness, pure water, and good sanitation as means of checking the spread of typhoid fever. He rightly lays especial emphasis upon the value of rapid diagnosis, and the necessity of destroying the infective material as soon as the disease is found to be typhoid fever. The fact has been proved again and again, that if typhoid excreta be not disinfected, that the disease will spread. Disinfection of the excreta is then the first and most essential step to be taken, after the other quite as obviously important point, that of correct and rapid diagnosis, has been decided.

The really valuable feature of Professor Koch's paper is the description of a mode of making a rapid diagnosis.

If the method of Drigalski and Conrad is as effective as Professor Koch declares it to be, there can be no doubt that a great addition has been made to the weapons of offence and defence in fighting typhoid fever. This has as yet to be proved by further and more extensive experiments. In the meantime it would be a distressing event if the promulgation of Professor Koch's views were to have the effect of rendering municipalities and individuals careless concerning water supplies and sanitation.

Pay every attention to the complete disinfection of fæces and urine, but at the same time the water supply and sanitation must not be neglected.

The duty of the physician at the present time, is to attack typhoid fever at its primary source, and of the sanitarian to prevent its spread by the strictest supervision of those agencies outside the human host which have been clearly demonstrated to be prominent factors in disseminating the disease.

THE PROGRESS OF MODERN MEDICINE.

The Edinburgh Review has an article on the advance made in medicine and surgery during the past century, the facts of which have been gathered from the "Life of Pasteur," "Memoirs of Sir Robert Christison," "Memoirs of Sir James Paget," "Life of Sir Charles Bell," "Life of Thomas Wakley," and other books. The writer of the article, referring to the most distinctive feature of present day medicine, says: "The note of modern medicine is precision. Everywhere, and by a variety of means, the physician seeks for precise knowledge. He is no longer content to be guided to a diagnosis by facial expression, and by his own unaided eyes and fingers. He looks, with the aid of modern instruments, into the eye, the larynx, and other organs; he measures the heart and the size of its cavities, listens to the sound of the chest, observes the reflexes, tests the nutritional condition of nerves and muscles, and records the temperature. With the help of a modern microscope he studies the blood. He asks, by all these new powers of observation, for a precise diagnosis, and having as he thinks found it, he demands from the pharmacologist or organic chemist, whom he can trust, to do precisely that to the organism which he wants done." The foregoing is an accurate description of the methods of the modern physician. He is able by means of instruments unthought of by his forefathers to make a diagnosis both quickly and surely.

Proceeding with his subject the author says: "Turning from the political and educational side of the question to the scientific, we see that about the middle of the century great advances were made in the evolution of modern medicine. Anæsthetics were discovered, and Virchow's 'Cellular Pathology' was published. Immediately resulting from the discovery of anæsthetics was the remarkable advance in abdominal surgery, beginning as it did with the revival of ovariotomy in the hands of Charles Clay, Spencer Wells, Baker Brown, and Thomas Keith. Pioneers in this direction had not been wanting in the pre-anæsthetic days. One of the most important of these, Dr. Ephraim McDowell, was an American."

It is pointed out, however, that the great glory of nineteenth century medicine was the revelation given to us by Pasteur and Lister as to the origin of many diseases, through the admission of germs, an advance which has revolutionized theory and practice in surgery and midwifery, and in many departments of medicine. The study of microorganisms developed almost as quickly as the rise of antiseptic surgery. Through the investigations of French and German biologists, in about the year 1880, it was found possible to separate the various bacteria, and the specific microorganism of tuberculosis, glanders, anthrax, tetanus, diphtheria, cholera, malaria, plague and influenza has been discovered, and its life history traced. The principle of toxins has been investigated, and these poisons have been isolated and studied. It has been also demonstrated, by means of experiments on animals, that antidotes to poisons in the system could be injected subcutaneously, and would exert a counteracting effect. To this discovery is due the antitoxic treatment of diphtheria. The writer, commenting upon the wonderful success of thus treating diphtheria, says: "Every step in such a research as this had to be tested over and over again upon humble animals before the results could be finally accepted. Therefore, every child saved by the antitoxic treatment of diphtheria owes its life to the scientific use of vivisection."

The article, which is a clear and comprehensive account of the forward movement of scientific and practical medicine during the past hundred years, but which is too long for more than a brief résumé in these pages, concludes with a eulogy of the schools of research in this country. The author says: "In the progress of medicine during the last twenty-five years the influence of the best universities in the United States, and in a smaller degree of those in Canada, has been a factor of considerable importance. The standard of work at, for instance, the Johns Hopkins University of Baltimore has conspicuously succeeded in influencing the best European workers on pathology, clinical medicine and surgery. The reason why certain universities in the United States have made their work felt so much more powerfully than any similar institution on this side of the Atlantic cannot be stated in a few words. It is a complex problem, made up of many factors. Among them, however, it is safe to say that the magnificent liberality shown by rich men and women in endowing some of the best universities in the States and Canada occupies an important place. Original research on any large scale is impossible in the absence of big endowments. The patient study of how to apply the results of research to clinical medicine and surgery is almost equally impossible without endowments. The best intellects of the age are wanted for progress in both these directions, and they cannot be had for the work if they are forced to allow themselves to be absorbed in the duty of earning a living on a lower intellectual plane. If England is to keep up with the United States in research and its applications to pathology and medicine large endowments must be forthcoming for Oxford and Cambridge and for the University of London. Failing them we shall have to be content with admiring the work done in the best American universities, and with taking a second place ourselves."

Such a thorough-going appreciation of the work of American medical scientists is seldom met with in British journals, where the habit is rather to give but grudging praise to the results of researches here. There is undoubtedly a bright future before the prominent American schools, and the day may come when in place of students going to Europe to sit at the feet of European medical Gamaliels, those in search of knowledge will flock from the other side to drink in scientific medical lore from the teachers in the United States.

THE MEDICINAL VALUE OF ALCOHOL.

THERE is at present practical agreement in the view that alcohol is not a necessary constituent of the ordinary dietary for a person in health, while on the other hand its indiscriminate, and particularly its excessive, use is a source of danger, quite apart from mere economic considerations. The discussion, however, as to the therapeutic utility of alcohol has been warm and protracted, and here considerable

diversity of opinion has been exhibited. The fact that alcohol when taken in small amounts is almost wholly consumed within the body indicates that it must have certain caloric value, but differences of opinion exist as to its physiologic effects. Some reflections upon this aspect of the subject have recently been recorded by the distinguished pharmacologist of Bonn, Prof. C. Binz (*Berliner klinische Wochenschrift*, January 19 and 26, 1903), who has shown that as a result of the administration of small amounts of alcohol both to lower animals and to man the respiratory activity is increased, as indicated by the amount of air that enters and makes its exit from the lungs within a unit of time. This increase occurs equally when the subject is drowsy and even asleep, and it is the more marked in the presence of hunger and of fatigue. The stimulating effect is the greater by reason of the presence of odorous substances. That the results noted are not due to reflex influences from irritation of the stomach was demonstrated experimentally. Observations of the blood-pressure showed also increase in correspondence with that in respiratory activity. It has further been shown that alcohol increases the secretion of gastric juice, in greatest degree when given by the mouth, but also when injected into the rectum. For the foregoing reasons it is believed that alcohol is a useful remedy in the presence of dangerous collapse, whether due to loss of blood, to internal disease or to wound-infection, whenever the breathing and the circulation are enfeebled. With reference to the dietetic value of alcohol, metabolism experiments by numerous recent investigators have shown that alcohol in small amounts and well diluted is capable of lessening nitrogenous disintegration and of taking the place of a corresponding amount of carbohydrates or of fat in the food.

From all that has been said upon this subject it would appear that while alcohol is not entirely devoid of dietetic and therapeutic value, this has been unduly exaggerated, and that, given under the proper conditions and in proper amount, alcohol is capable of stimulating respiration, circulation, and digestion, and to a certain degree also of subserving the purposes of a food and of supplying a certain amount of heat. This, further, is the position that it seems the pendulum must reach after its swing to either extreme.

THE INTOXICATION PSYCHOSIS DUE TO IODOFORM.

In the *Deutsche Medizinal-Zeitung* for February 2 and 5, 1903, Dr. Hans Schwerin discusses the above subject. After giving the history of iodoform in its chemical and pharmacological relations, the author discusses its employment with special reference to its use by internal administration and by injection into the bladder for the purpose of rendering purulent, decomposing urine aseptic. The patient, a man aged sixty-five, with slight arteriosclerosis and a tendency to melancholic ideas, somewhat nervous, but previously mentally sound, four weeks after a successful Bottini operation, was suddenly seized with mental confusion of high grade, strong excitement, hallucinations, and ideas of persecution, the first symptoms appeared after the injection of iodoform into the bladder for eight days, the amount being in all *ad maximum* 12 gms. Discussed in the light of Picque's post-operative pyschoses, this can hardly be classed as such, inasmuch as it came on after so long an interval. Senile dementia is excluded by the recovery. The senile form of acute hallucinatory confusion characterized by sudden onset, predominance of anxious change of disposition, striking weakness of effect in comparison with the delusions, smaller motor excitement, and great intellectual and bodily exhaustibility, can proceed to cure. As, however, the cerebral phenomena (according to Furstner, loss of consciousness, transitory aphasic symptoms, and other marks of severe cerebral circulatory disturbance), frequent in that form, were lacking, and as, moreover, this form is rare, it seems unjustifiable to include the case in this category. And by the agreement of this case with those heretofore reported as iodoform intoxications, we are warranted in placing it there. As described by Hadley and by Obersteiner, this intoxication has the marks characteristic of a recurring, often restless and anxious confusion, with, in light cases, a change of character, an inclination to weeping, and many times pronounced melancholy. In the higher grades there is mistaking of the surroundings, with mostly an anxious unrest; delirium of apparently terrifying content causes the patient to spring up; he wishes to flee, to get out of the window, to jump into water, and is often aggressive and violent. Such conditions appear suddenly and especially at night, and many times quiet days and restless nights alternate. After the attacks, which last some hours or days, the patients come to themselves often suddenly as though out of a dream, or gradually and, as a rule, with amnesia for the attack. Krafft-Ebing and Lewins describe the psychosis similarly. Schwerin adds that the pulse is constantly and considerably accelerated. Another consideration which clinched the diagnosis was the fact that the psychosis ceased abruptly, coincident with the disappearance of the iodin from the urine. The author emphasizes the fact that, whereas usually iodin appears in the urine as iodides, here it was found exclusively in organic combination; that is, it first responded to tests after evaporation to dryness and incineration, and he cites several cases reported by urinalysts in which iodin was found only under these conditions. While still on the twenty-first day confusion existed, and iodin, of course in diminished amount, was found in the urine, on the twenty-sixth day the patient was perfectly normal mentally and no iodin could be detected. The author refers to the discussion in the literature as to whether the toxic action of iodoform is the equivalent of that of iodin, and cites especially Harnack's observation in 1882, that iodoform psychoses occur only when the iodin is excreted in organic combination, or at least in a form which is demonstrable only after incineration of the evaporated urine. Whether this is an organic combination or, as Quaedvlig and Zeehuisen believe, inorganic compounds of iodin intermediate between iodides and iodates, matters not so much. The author then discusses the amount probably required to intoxicate. Given that during eight days the patient had received *ad maximum* 8 grams per day, the author calculates that at least one-fourth to one-third must have been expelled by urination, but

that owing to its high specific gravity much probably sank into the deepest part of the bladder, in which 4-29 c.cm. of residual were found. In the early days the surgeons used from 60 to 150 grams on one bandage but, fatal cases accumulating, König, as the result of experimental researches, placed 10 gms. as the limit of safety, as some persons show unusual sensitiveness to the drug. The author then gives a table of the amounts used by various surgeons by injection into the bladder, and concludes that as the amount used in his case was not excessive, other causes must be invoked. The injections were not sterilized, and Stubenrauch has shown that decomposition of the iodoform favors intoxication. The principal factor was, however, probably the local conditions, for Behring has demonstrated that blood through its oxygen, and pus through the contained microorganisms, are able, at body temperatures, to form in a short time from iodoform a number of loose iodin combinations. Then, too, the local conditions favored resorption for the three Bottini wounds, 4, 3.6, and 2.2 cm. long, were granulating, and Holger Mygind has shown, experimentally, that in this stage wounds absorb iodoform more readily than when fresh.

Discussion on Malaria and Yellow Fever at the Egyptian Medical Congress.

One of the most valuable and interesting discussions at the Egyptian Medical Congress was that on malaria and yellow fever, of which the *Lancet*, February 28, gives a summary. Major Ronald Ross, who was unable to be present himself, sent a paper. In the course of his remarks he declared his belief that the most important question now to decide is as to whether the gnats which do not belong to the genus Anopheles are or are not concerned in the propagation of malaria, and why certain individuals of one species of gnat are more dangerous than others. For instance, the researches of Stephens and Christophers demonstrate that the Anopheles Rossii may be almost exculpated as an agent of malaria. His own personal experience of three years' constant attention to the subject, in countries so different as water-logged Assam and Lagos on the one hand and arid Ismailia on the other, has led him to believe that the best personal prophylaxis is the ordinary mosquito-net during sleep, and to this he adds the prophylactic administration of quinine when the danger is especially great. As mosquitos seldom bite in the open air it seems an unnecessary policy to avoid them there, but he praises very highly the use of the punkah or the electric fan, together with the wholesale removal of breeding-places of all kinds of mosquitos.

Dr. Montaldo (Spanish Navy) read a paper based on his experience of malaria in the island of Fernando Po. He said that he was not at all converted to the mosquito theory, but believed chiefly in general hygiene and in the prophylactic use of valerianate or hydrochlorate of quinine, which he recommended in doses of from four to eight grains taken fasting before bedtime. Professor Mariani (Genoa) in a long speech praised the work of the Italians in elucidating the malaria problem, and complained that Professor Koch and others had not given them sufficient acknowledgement. Professor G. Gaglio recommended very highly the hypodermic injection of quinine, which he gives with urethane in the proportion of two of hydrochlorate of quinine to one of the latter. Major Gorgas of the United States Army Medical Corps contributed a paper on sanitation and yellow fever in Cuba, a matter which has been fully dealt with in the Medical Record. With regard to the ability to destroy mosquito larvæ on a large scale, Major Gorgas said that in January, 1901, just before the mosquito brigades were organized, an inspection of the whole city showed that mosquito larvæ existed in 26,000 different places in the city. A year later a similar inspection showed less than 300 deposits of larvæ in the same area.

In the same edition of the *Lancet* as the foregoing report appeared, is a description by Major Ross of what he deems the most effective mode of wiping out malaria. He thinks that measures taken to destroy larvæ and anopheletes is a better plan than dosing every one indiscriminately with quinine, or than leaving the natives callously to their fate, and especially than by attempting to protect Europeans by mosquito-proof houses. He also proffers the advice that not only the anopheles but also the culex should be summarily destroyed, as the culex pipiens and the stegomyia fasciata are capable of propagating elephantiasis and yellow fever.

In the discussion at Cairo nothing new with regard to malaria or yellow fever was brought forward, but the old ground was carefully gone over. There can be no doubt that the advice of Major Ross as to exterminating the anopheles, culex pipiens, and stegomyia mosquito is excellent, and, if possible, would quickly do away with malaria, elephantiasis, and yellow fever. How to destroy the anopheles species, however, is a problem hard to solve. At present, at any rate, we must rest content with employing every means in our power to wipe out these disease-bearing gnats in towns and in the neighborhood of towns, which is probably what Major Ross means. At the same time, the judicious use of quinine must not be neglected. It would seem, from the success attained in Cuba, that the day is in sight when yellow fever will be practically extinct, but the scope of yellow fever is limited, indeed, compared with malaria.

The Doctor's Bills.

In the *Medical Mirror*, January, Dr. Robert T. Morris discourses instructively concerning a matter of the greatest interest to the medical practitioner, that of his bills. It is a sad, but well-known fact that no profession suffers as does the medical in the matter of receiving adequate payment for services rendered, and the doctor is almost always the last to be paid. Dr. Morris points out that a man, in order to be well qualified to fulfill the duties of a physician or surgeon, must gain the requisite knowledge at great expense, and not only this, but when in practice he must keep himself *au courant* with the latest discoveries, new modes of operation or treatment and most recent literature pertaining to his profession. The life of a successful medical man is an arduous one, and calls for a continual drain upon his mental and physical resources, as well as upon his pocket. To lead such a strenuous existence—even if he be of iron constitution—he needs a vacation of at least two months in the year. When at home, too, he must live in good style, dress well, and in all respects sustain the dignity of his calling. It therefore is a self evident fact that the doctor should be well remunerated, and that his bills should be paid promptly.

The majority of medical men, however, if asked would undoubtedly say that the money due to them does not come in so rapidly as they could wish. Dr. Morris places his finger on one of the weak spots

in a doctor's makeup when he refers to leniency in charges and carelessness in collecting bills, and demonstrates the fallacy of so doing. His patients understand his motives, and can classify him accurately. In the writer's own words: "If he is too lenient in making charges and too slack about collecting bills, they understand that he is not putting himself in position to render them the very best sort of service, because they know that he cannot prepare himself for rendering the best service. If the doctor prepares himself for giving large services in a large way, he is at once in demand by the sort of people who are in the habit of making use of that sort of service in their lawyers and engineers." As to the charging of large fees, Dr. Morris thinks that such a procedure is quite right when the patient has received from the treatment beneficial effects, which has, perhaps, enabled him to continue in the control of a large business to his consequent great pecuniary advantage. If a rich man calls in a well-known physician he must expect to pay as much for the expert knowledge in safeguarding his health as he would to a lawyer for assisting him to advance his material interests.

Dr. Morris concludes as follows:

"While the conditions in the smaller towns are different from those in the cities, the principles remain the same, and the physician who has expensively prepared himself for good work, or who out of experience has developed into a skilful physician, has a right to ask for compensation freely and promptly, without in the least including any mercenary motives. His bills should be regularly sent out at least once a month, and if not paid by the end of the third month should go to the collector, unless the patient states a reason why such a business proceeding should not be applied in his case. If the reason is a good one, there are very few physicians indeed who cannot be depended upon to respect it, and to make the most kindly and generous disposition of the account. The important thing is to bring the matter to a business point in a business way at an early date, in order to give the doctor opportunity to be kind to his patient or just to himself. Lastly, a physician should never look after his books himself. His judgment on the subject of accounts is not so good as that of an outsider, and a paid secretary will earn twice as much as his salary in actual figures, aside from time and trouble saving, in the office of any physician."

The remarks of Dr. Morris are sound, and although, perhaps, his advice applies more closely to the great men of the medical profession than to its rank and file, yet much of his article may be taken to heart by all its members. It should be clearly understood that a man is by no means a worse doctor because he is a good business man. He will be better appreciated by the general public, and will benefit from a pecuniary point of view.

Insanitary Condition of the British Houses of Parliament.

For many years there have been grave complaints, on the part of its members, concerning the defective ventilation, ineffective drainage, and general insalubrity of the British Houses of Parliament, and especially of the House of Commons. According to recent accounts, matters in these respects seem to have gone from bad to worse, or, at least, have not improved. In *Mainly About People*, a well-known weekly journal published in London by a distinguished Member of Parliament, is a harrowing description of the ills with which the British legislator has to contend while in the performance of his duties. The writer says, in part: "The old idea of the House of Commons, that it was the best club in London, has received some severe shakes during the last few years. For instance, it was found, whenever there was an epidemic of influenza, that members of the House of Commons were among the first and worst victims. Committee after committee has sat on the drainage of the House; in nearly every case it has pronounced against it. Often the odors in the House have been found almost intolerable. I remember one night, when Lord Randolph Churchill was leader of the House, that he consented to an adjournment, on the express statement that he found the odors around the Treasury Bench so sickening that he was no longer able to stay in his place." It appears there is a form of headache known as "the House of Commons headache," and that attendance for any length of time in that legislative chamber produces such a feeling of lassitude and general malaise that only the strongest are able to be in their places as often as required without breaking down. Last year most of the Ministers fell ill, and the writer in *Mainly About People* declares that there were occasions when there were nearly as many absentees from the Treasury Bench as attendants. Undoubtedly there must be something radically wrong either with the situation of the building, its drainage, or its ventilation to account for this manifest unhealthiness. It seems somewhat curious that England, the pioneer country in sanitation, and where this science is supposed to have attained its highest development, should not place "the mother of parliaments" amid hygienic surroundings.

Housing of the London Poor.

The recrudescence of the tenement question in New York has aroused interest in the manner in which other large cities house their poor. Of course it is well understood that the problem of how to house the poor cheaply, efficiently, and under good sanitary conditions has not been satisfactorily solved anywhere, but it may be said that several large centers of population in Europe have come nearer to a successful solution than has New York. Glasgow, perhaps, treats her poor with greater intelligence than any other city. There, the gas, the water supply, the means of street locomotion, and to some extent the housing of the poor, are under municipal control, and the system is stated to work excellently well. The County Council of London, within recent years, has erected nuerous model tenement dwellings for the poor in that overgrown city, with a fair measure of success. In the annual report, 1901, of the Medical Officer of Health of the Administrative County of London, just published, are some useful details regarding the influence upon health and morality exerted by the development of tenement building. Mr. Shirley Murphy, the officer in question, says that "Tenements of less than five rooms have diminished in number, the fall being particularly apparent in the case of single-roomed tenements, The average number of occupants per room has also declined in all classes of dwellings, but the greatest decline has again been manifest in the case of tenements of only a single room. The relative number of so-called 'overcrowded' tenements, and also the number of their occupants in the poorer parts of London, showed a considerable reduction in 1901, as compared with the previous year." It is gathered from this report that a considerable improvement has taken place in the manner in which the people of London were housed

in 1901, in comparison with 1891—that is to say, overcrowding in the whole of the metropolis has declined in the past ten years as regards both quantity and intensity.

The *London Hospital*, February 28, referring to this matter, preaches the gospel of cleanliness—perhaps, believing with John Wesley that "cleanliness is next to godliness." Speaking of the dirtiness of London tenants, our esteemed contemporary says: "In point of fact, the question is very largely one of cleanliness; and the schools and county council, together, might effect a revolution in the habits of the working classes of London, in this respect, and might bring them up to some approach to the American standard. The County Council admits into its tram-cars, without hindrance, men in filthy working clothes, whose faces and hands are black with grease and grime, and who both leave stains upon any seat which they occupy and soil in a corresponding manner the clothes of any passenger who either succeed them, or is pressed against them. No American workman would show himself in public in such a condition; and if the council and the schools would particularly teach adults and children that personal filth is disgraceful, an increased demand for decent houses would before long follow from a demand for personal cleanliness." Undoubtedly, the extremely dirty, personal habits of a large proportion of the poor population of London tells against the healthiness of the dwellings which they occupy, but at the same time it is gratifying to learn from Dr. Murphy's report that the better housing of the poor has been attended with results beneficial to health and morals. Although New York has nothing to learn from London so far as cleanliness is concerned, her municipal authorities and philanthropists might copy with advantage the policy of the London County Council in erecting cheap and sanitary dwellings for the poor. The housing of the poor—it may be prophesied—will at no very distant date be regarded as a municipal affair by most large cities.

Treatment of Epileptics.

Dr. Fletcher Beach contributes to the *Lancet*, February 28, a paper on the treatment of epileptics, which is, in fact, his contribution to the discussion upon epilepsy, which recently took place before the Medical Society of London. Dr. Beach points out that in that discussion no mention was made of errors of refraction as a cause of epilepsy. The writer remarks that Mr. Work Dodd, in the sixteenth volume of "Brain", showed that this might be the cause. He examined one hundred consecutive cases of epilepsy, and found that by correcting the errors of refraction in combination with other treatment, forty-nine were cured or relieved. Dr. Beach agrees with Dr. Russell, Dr. Beevor, and others that a toxic cause of epilepsy has not been proved. With reference to treatment by drugs, he is in favor of giving large doses of the bromide. and prefers the combination of ammonium, sodium, and potassium. When this combination is not desirable, and only one salt required, Dr. Beach gives the bromide of ammonium, as it is not so depressing as the bromide of potassium As to the length of time during which the bromide should be administered, the writer is in favor of giving it for two years after the last fit in ordinary cases, and for three years in a few cases in which circumstances render it necessary. He is a firm believer in the colony treatment, and is at one with other authorities in thinking that a healthy out-of-door life, with occupation and good diet, together with the administration of bromide and suitable tonics, is the most effective and intelligent treatment of epilepsy. Errors of refraction were thought at one time to be important factors in the causation of epilepsy, but this view is no longer widely held; indeed, the origin of epilepsy is still unknown, although a very large number of neurologists are of the opinion that it proceeds from an autointoxication.

News of the Week.

An American Quack Doctor in Europe.—"Dr." J. H. Nicholson, said to be an American, was arraigned in the Bow Street Police Court, London, on March 21, on charges of fraud preferred from Berlin. Nicholson has had a long career as a quack on the European continent, and when he was first arrested he said that he was a native of Philadelphia, and had practised as a physician in New York. He afterward said that he was a Canadian. The magistrate finally decided that Nicholson was an American and granted his extradition to Germany. There are numerous charges of fraud against him.

Fighting Tuberculosis in Great Britain.—The British National Association for the Prevention of Consumption has just been held. The two prominent features of the meeting were the announcement of a gift of $200,000 for the erection of a sanatorium, and the other a particularly eloquent speech by the orator of the medical profession in Great Britain, Sir James Crichton Browne. The speaker expressed his conviction that the day was coming when the terrible scourge of tuberculosis would be eradicated.

Natives of India Refuse to Kill Rats.—According to the *Allahabad Pioneer*, a municipal committee that was appointed to take precautions against the spread of the plague at Amritsar initiated comprehensive plans to exterminate rats. The committee was immediately faced by a difficulty arising from the scruples of the natives, whose religious tenets forbid the taking of life, and consequently the committee was compelled to offer a reward for live rats, which will be maintained comfortably at public expense until the plague is suppressed, when, presumably, the rodents will be released. The municipality has authorized the expenditure of forty-two rupees a month for the board of the rats while the scheme is being tried.—*New York Sun.*

School and Churches Closed on Account of Smallpox.—Many cases of smallpox have been recently reported from the village of Davenport, Delaware County. The school has been closed and the village churches are not open for service.

Death from Glanders.—Benjamin Hilson, a cigarmaker, died on March 20, in the Metropolitan Hospital on Blackwell's Island, of glanders. He cut his finger on Washington's Birthday, and it is supposed the wound became infected through coming into the vicinity of horses suffering from the disease.

Clara Barton May Be Retired.—It is reported that, as a result of recent conferences of the Executive Board of the American National Red Cross Society, Miss Clara Barton will be relieved of active control of the organization. The statement is made that the new executive will be Rear-Admiral William K. Van Reypen, U.S.N., retired, formerly Surgeon-General of the navy. Miss Barton's retirement is declared to be an absolutely essential step toward restoring harmony among the members of the Red Cross Society. In addition to this reason, it is

pointed out that a new and energetic executive is badly needed in order to place the organization on a proper footing. It is proposed to call a meeting of the board of trustees of the Red Cross Society at Washington shortly, when it is expected that the recommendation of the executive committee will be confirmed. Miss Barton, as matters now stand, holds the presidency for life, and possesses absolute control of the society. There has been recently somewhat acute dissatisfaction with the high-handed manner in which Miss Barton has used the power placed in her hands, and this feeling culminated a short time ago in a memorial presented to Congress protesting against the continuance of supreme control being vested in Miss Barton. It was also stated that under such conditions neither the President nor the members of his Cabinet would serve on the board of consultation. As, however, an article in the constitution of the Red Cross Society requires that the President and Cabinet should be members of the Board of Consultation, their retirement brought up the question as to whether, in the event of their refusal to serve, the charter would not be nullified. The recent conferences had for their chief object the securing of the promise of President Roosevelt and his Cabinet to again take their seats at the board of consultation.

The Drink Question in London.—The New York *Sun*, March 22, in its London letter quotes figures which are being published, showing that the drinking facilities in many places are out of proportion to anything needed. In the metropolitan area of London, for example, there are 14,353 licenses, giving one to every 446 inhabitants, in spite of the fact that districts are included where there is only one license to over 1,600. In Holborn there is one public house to every 257 inhabitants; in Westminster, one to every 327; in Finsbury, one to every 364; and in Stepney, one to every 394. To put it in another way, it is found that there are 486 public houses per square mile in Holborn; 798 in St. James'; 379 in Finsbury, and 349 in Marylebone. One map is published of a certain nine-sixteenths of a square mile, where there is a public house, not including hotels and restaurants, for every seventeen inhabited houses. Assuming that the male adult population is normal, there is one public house for every twenty-two men in the strand licensing division, and one for every sixty-eight in Marylebone.

Man's Superior Brain.—A cable despatch to the New York *Sun*, March 22, reports the following: Professor Marchand of Marburg has accumulated the largest number of brain weights ever published. He gives a thorough analysis of 1,169 cases. He says he finds the average weight of the brain of a male child at birth is 360 gms., and of a female child 353 gms. Although Professor Marchand shows a certain relation between stature and brain weight, the relation is very inconstant. He concludes that the lesser weight of a woman's brain is not alone dependent on her smaller stature, as a comparison of both sexes of the same stature show that the male brain is invariably heavier. In a growing child, until it reaches a stature of 70 cm., the brain weight increases proportionately with the body length, irrespective of age or sex. After that the male brain begins to outstrip the female. The maximum brain weight is usually attained about the twentieth year, when the male's average is about 1,400 gms. The female maximum is usually reached about the seventeenth year, when the average is 1,275 gms.

Christian Science Investments.—The Christian Scientists, or, rather, those at the head of that sect, have contrived to amass a considerable amount of money. It has just been announced that the Christian Science Board of Directors, consisting of Ira O. Knapp, William B. Johnson, and Joseph Armstrong of Boston, and Stephen A. Chase of Fall River, has acquired title to a large extent of property in Boston. It is agreed that the transfer is made subject to conditions imposed by Mary Baker G. Eddy on the grantees named in September, 1892. Another stipulation is that no new tenet or law can be amended or annulled by the grantees without the consent of Mrs. Eddy.

Experiments with Formalin in Boston.—Dr. Hill of the Boston Health Department laboratory has been recently testing formalin as a remedy for blood-poisoning, and reports that he has found it to be of no use. Four rabbits were experimented upon, two of which had the bubonic plague and two the glanders. One of each was treated with formalin, and they died before the two that had not been treated at all. The formalin did not destroy the germs, but became absorbed in the tissues, and injured them more than the organisms which it was intended to attack.

Dedication of Cochran Surgical Pavilion.—At Yonkers, on March 21, the Cochran Surgical Pavilion was dedicated. The building was erected as an annex to St. John's Riverside Hospital with money left for the purpose by the late William Francis Cochran, who also provided the money to build the hospital itself. The new building is about seventy feet long by fifty feet wide, and three stories high, and is said to be one of the best equipped in the country.

New British Military Hospital.—The new Military Hospital, now being erected on part of the site of the old Milbank prison, will afford largely increased accommodation for soldier patients. It is part of a considerable scheme of building which the War Office has in process of completion at Milbank. Already the new Army Service Corps barracks are occupied, and the hospital, which affords room for some 200 beds, will soon be finished. The hospital part of the scheme is estimated to cost £100,000 ($500,000). It includes six separate blocks of buildings, carried out in red brick, with string courses and dressings of sandstone much after the style of St. Thomas's Hospital, and, as in the case of that great institution, there is provided suitable covered communication between the component blocks of the hospital.

A Fever Hospital Set on Fire.—Six attempts within a week have been made to fire the Edinburgh Fever Hospital. The first attempt was made with a barrel of paraffin oil. Four other outbreaks occurred behind doors, and the sixth attempt was made to fire the buildings.

Legacies to Charity.—The Paterson Orphan Asylum, the Catholic Orphan Asylum, the Paterson General Hospital, and St. Joseph's Hospital, each benefit to the extent of $25,000 by the death of William Laverack, a jeweller of Paterson.

X-Rays in the Spectrum.—Lord Rayleigh, professor of natural philosophy at the British Royal Institution, has announced that M. Blondelot, a skilful French experimenter, very recently adduced evidence going far to prove that the Röntgen rays are susceptible of polarization, if they have not been polarized already, and can therefore be traced in the spectrum. If this is true and the rays are transversal, as M. Blondelot thinks, it follows that they are a species of ordinary light, but of extremely short wave lengths, perhaps a hundred times shorter than the waves of the light that one can see. Lord

Rayleigh said he saw no reason to question the discovery, which is of first-rate importance in helping to determine the nature of the Röntgen rays, which has been in doubt ever since they were discovered.—*New York Sun.*

Tuberculosis Society in Washington.—A society of physicians, clergymen, and others has been established in Washington for the purpose of conducting a campaign of education in regard to tuberculosis. The society purposes to raise funds to carry on a systematic diffusion of knowledge about tuberculosis, its prevention and the relief of those who are afflicted, by means of public lectures, leaflets, and scientific documents. The work will also be made the subject of special instruction in the public schools.

Ordinance against Expectoration.—The Philadelphia Councils have passed and the Mayor has signed an ordinance declaring expectoration on the sidewalks, in public conveyances, and in other places resorted to by the public, a nuisance and prejudicial to health, the offender or offenders being liable to a fine of one dollar and costs for each violation.

The Philadelphia Society of Tropical Medicine has been organized with the special object of preparing students of medicine and physicians for service in the tropical dependencies of the United States, and the following officers have been elected: *President*, Dr. Thos. H. Fenton; *Vice-Presidents*, Drs. James C. Wilson and James Anders; *Secretary*, Dr. Joseph McFarland; *Treasurer*, Dr. E. B. Gleason; *Executive Committee*, Dr. John V. Shoemaker, chairman, and Drs. T. H. Fenton, Judson Deland, R. G. Curtin, Orville Horwitz, and Hobart A. Hare.

"Biochemisches Centralblatt."—A journal with this title has been established in Berlin under the editorial direction of Professors Ehrlich, Fischer, Kossel, Liebreich, Muller, Proskauer, Salkowski, and Zuntz. The object of the publication will be to report such chemical experiments and observations as are of importance to the physician; the study of plant physiology; of physiological chemistry; of the chemistry of the tissues and organs under normal and pathological conditions; of the chemistry of digestion, the secretions and excretions, metabolism, and the blood; of ferments and fermentations; of the chemistry of the pathogenic microorganisms (toxins, antitoxins), and the phenomena of immunity; of toxicology and pharmacology; and of hygienic chemistry, disinfection, and the examination of water. The American editor, to whom abstracts of papers on the subjects appearing in journals of this country and Canada should be sent, is Dr. Heinrich Stern, 56 East Seventy-sixth Street, New York City.

Obituary Notes.—Mrs. Ellen Hastings Scrimgeour, President of the Women's Health Protective Association of Brooklyn, died at her home in that city on March 21. She had been suffering from Bright's disease for some months. The deceased lady was sixty-eight years of age, and had been actively engaged for the past twenty years in woman's work in Brooklyn.

Dr. J. Augustus Carncross, assistant physician to the Friends' Asylum for the Insane at Frankford, Philadelphia, died on March 19 from heart failure, at the age of fifty-eight years. He was graduated from Jefferson Medical College in 1876, and he had been assistant physician in the State Hospital for the Insane at Warren, Pa., and in the Philadelphia Hospital.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

BART'S—ANKYLOSTOMIASIS—VOLKMAN'S CONTRACTURE—DISLOCATION OF TENDON—VARICOSITY IN CHILD—GRAVES'S DISEASE—LATENT EMPYEMA—HEMORRHAGIC TYPHOID—THE ROYAL ORTHOPEDIC AGAIN—CORONERS—PARLIAMENT—HOSPITALS ASSOCIATION.

London, March 6, 1903.

Old Bart's is to remain on the site it has so long occupied. At least that was the decision of the Lord Mayor's Committee by an almost unanimous vote on Monday last. The Lord Mayor again presided, and after a prolonged discussion of the evidence brought forward at the four previous meetings, the following resolution was passed by fourteen votes to one: "That, in the opinion of this committee it is desirable in the public interest to retain St. Bartholomew's Hospital on its present site." It was then decided to form two subcommittees, one to deal with buildings, the other with administration and finance, in order thoroughly to investigate the best means of providing a hospital, perfect in every detail and brought up to the latest requirements of modern scientific knowledge, on the present site of the hospital. Each subcommittee will meet once a week until their investigations are complete.

Sir. Wm. Church, President of the Royal College of Physicians, presided, on Wednesday, over the annual meeting of the "after-care association." This is the only charity of the kind in the kingdom. It takes care of poor persons discharged on recovery from lunatic asylums, boarding them out in the country under proper care and supervision, or placing them in convalescent homes. Grants of money and clothing are also made to some, and others are assisted to obtain suitable employment. It is obvious that such work is deserving of encouragement, and Sir W. Church was supported by Drs. Savage, Claye-Shaw, Henry Rayner, Robert Jones, and others. It was stated that the patients who had been assisted had shown great gratitude. The proportion of relapses was also said to be less where the patients had been in convalescent homes. The society received, in 1902, a total sum of £772, but a part of this was from exceptional sources, and increased subscriptions could be well employed.

Ankylostomiasis, as your reporter of the Egyptian Congress remarked, "must be remembered in seeking for the cause of obscure cases of anæmia, even in America and England." We have just had an illustration of this in the shape of an interim report to the Home Secretary on the Cornish mines. Dr. Haldane, F.R.S., was instructed to make an inquiry (with Mr. J. S. Martin, his Majesty's Inspector of Mines), and he found among the men employed in the Dolcoath Mine that for several years some of them had suffered from a state which they named the "Dolcoath disease." They were anæmic, became faint on exertion, and suffered from palpitation. Pustular eruptions and other complications were common. Intercurrent diseases, such as pneumonia or phthisis, carried off some of the patients, and others had dropsy. Neglected cases were apt to end in cardiac failure. Heart disease was sometimes blamed. Dr. Haldane came to the conclusion that the disease was ankylostomiasis. Common in Egypt and called "Egyptian chlorosis," its nature was determined in 1854, and it was soon after recognized in Brazil and most tropical and subtropical countries. When it appeared among the workmen engaged in making the St. Gothard tunnel it excited more attention, and recently Dr. Manson observed cases among the Lascars employed at the docks. It is supposed that the disease was introduced by miners who had been employed for a time abroad and afterward returned to their former work. The conditions for its spread are favorable, the temperature is high in the mines, at one level, Dr. Haldane found it was 79° F. Three or four years ago the manager of Dolcoath improved the ventilation and attempted disinfection with large quantities of chloride of lime and permanganate of potash. These measures are approved by Dr. Haldane, whose recommendations are in the direction of securing good ventilation and cleanliness.

Among the cases exhibited on Friday at the Clinical Society, I may mention some of considerable interest. There were three, for instance, of Volkman's contracture—one a child, aged five years, treated for two years by passive movements, massage, and Faradism. Only slight improvement was claimed. Another, a boy, aged nine years; injury to forearm two and a half years ago. Several operations, without result, massage, etc. Ultimately resection of one-half to three-quarters inch of both radius and ulna from posterior aspect of middle of each shaft; wired bones united, then massage; result, great improve-

ment. The third case was a boy, eight years old, similar operation with similar result.

A man, thirty-seven years old, was shown (by Mr. Betham Robinson), who had the head of the left humerus excised in St. Thomas's hospital, on account of recurrent dislocation, which had occurred nine times in three years. Six months ago he fractured the clavicle, which united rapidly. On January 3 he fell from a van, could not bring the arm to his side properly. Finds it takes this position at times, but is sometimes natural.

The humerus is abducted and inwardly rotated to a slight extent; the shoulder-joint being then fixed, attempted movement is attended by rotation of the scapula. The head is felt in the axilla and more prominent against the front of the capsule than normally.

The position is easily rectified by fixing scapula, and bringing elbow forward to relax the biceps, and then rotating outward. Mr. Betham Robinson suggested that the condition was associated with abnormal laxity of the capsule and increased play of the tendon in its groove. In abduction with inward rotation, the tendon slips over the great tuberosity, and at the same time the head of the bone is brought up against the front of the capsule at the anterior margin of the glenoid cavity.

Mr. Gould suggested hypertrophied synovial fringe as the cause. Mr. Marsh doubted whether it was dislocation of the long tendon, which usually took place inward, not outward. He thought the case should be thoroughly investigated.

Mr. Betham Robinson replied that the joint could be explored, but if it proved to be dislocation of the tendon, what should be done? He hardly thought it necessary to remove the head of the bone, as on the other side.

A little girl of seven years, shown by Mr. Kellock, had enlargement of the right internal saphena vein at the upper part. Varicosity was also seen at the side and front of the patella, behind the internal malleolus and over the inner side of the foot. Mr. Gould said he had never seen varicosity in so young a female, though varicocele was met with in male children. He thought the case supported his view of the cause of varicosity. Mr. H. Cripps, noticing that the foot looked bigger than its fellow, and the limb longer, suggested incipient giantism. Mr. Kellock admitted the limb was one-quarter inch longer, but there was no indication of enlarged lymphatics, and he proposed to remove a piece of vein above.

Dr. Batty Shaw showed a case of Graves's disease in a railway porter of forty-six years, whose son, aged twenty-one years, is also affected. Dr. Phillips said he had met with the disease in mother and daughter.

A paper on "latent empyema in infants" was discussed at the Royal Medico-Chirurgical Society. The adjective is scarcely appropriate, for the cases described were rather those in which the difficulties of diagnosis are such that the condition is often overlooked. An irregular raised temperature, with symptoms pointing to the respiratory system, should excite suspicion. The physical signs are often ill-defined or obscured by complications, but the disease is evidently serious, and the majority of the cases are fatal. The diagnosis from tuberculosis is especially difficult, but the long course with prevailing high temperature, often 103° F., may be noted. The difficulty usually arises from a small sacculated empyema in a position where it may be obscured. Thus the commonest situation is at the extreme posterior base, where the liver or stomach may interfere with the signs. As to small interlobular empyemata, it is almost, if not quite, impossible to diagnose them, for there may be only a thin layer of pus between the lobes. The spread of the infective agent may give rise to purulent pericarditis, meningitis, peritonitis, arthritis, etc. Several speakers thought repeated explorations with the needle should be made in doubtful cases, and one said the insertion of the needle did not give rise to much pain. Perhaps the children might have a different opinion. Even so, no doubt exploration must be resorted to. Possibly in some cases the *x*-rays may come to our aid. Some recommended resection of a portion of a rib, and one thought this operation rendered it possible to explore every part of the lung, but this was disputed, as in these cases the adhesions were considerable, and little would be gained unless the cavity of the empyema were opened. A case was mentioned in which a child died, apparently from the operation. Others were mentioned in which explorations had been futile, but resection enabled the pus to be found and evacuated. One physician had seen cases in which the temperature was normal or subnormal throughout the whole course of the disease.

Two cases of hemorrhagic typhoid were described by Dr. K. Fowler and Mr. Foulerton at the Medical Society with full bacteriological details. They admitted that their cases shed little light on the pathology. One case showed that in a severe case no other organism than the bacillus typhosus might be present, and that the mixed infection observed in other cases was not an essential feature. Widal's test was negative in both cases, and it was held that if this gave no reaction after twelve days' illness it was either not typhoid or else it was an extremely severe one. Dr. Wright said typhoid vaccine diminished the coagulability of the blood, so did diminished alkalinity, and suggested such cases should be tested in both these respects. Calcium chloride was only of use by combining with fibrinogen, but in typhoid fever this was diminished or wanting.

Dr. A. Voelcker regretted that the coagulability had not been estimated in these cases. He had seen a case of gastric ulcer with hemorrhage in which there was a marked diminution. Mr. Foulerton replied that in one of the cases the blood coagulated readily.

You will remember the scandal about the Royal Orthopædic Hospital. The managers have added another proof of their unfitness for their position. In a mean, underhand way, they have got rid of their chief surgeon. He did not agree with their views about removing the hospital. So, at the annual meeting, they omitted his name from the officers to be reëlected. He has served the hospital for more than twenty years. I think it must be nearly thirty. But the new committee does not care, and treats thus the one man who was an ornament to the staff. More will, perhaps, be heard of this.

Coroner Troutbeck is not to have everything his own way. The deputations to the County Council have had some effect, and a circular has been issued in which the council state that it is in special cases that a pathologist should be called in—a plan the practitioners concerned have always themselves recommended.

Not much of medical interest has come before the new session of Parliament. Sir Batty Tuke has introduced the Medical Acts Amendment Bill of the Medical Council. The Prime Minister has announced the intention to prolong the vaccination act for a year. Questions relating to the smallpox epidemic, dangerous shellfish, public health, etc., are to have some attention, but much depends on the time that can be spared from great political questions.

Some newspapers have been trying to get up a sensation about an alleged bicentenarian, who is said to be in hospital at Tomsk, and all sorts of talk about old age is being indulged in.

Sir H. Burdett addressed the Hospitals Association on Tuesday on the question whether some hospital should not be removed to other localities, and if so, which. He is in favor of the amalgamation of some hospitals.

LETTER FROM ZURICH.

THE ANALOGUE OF THE OSTEOPATH IN SWITZERLAND—TREATMENT OF PUERPERAL FEVER—EFFECTS OF HIGH ALTITUDES ON ELDERLY PERSONS—TREATMENT OF GALLSTONES.

ZURICH, March 1, 1903.

THE event which is occupying the medical mind, and also part of the lay press, in Switzerland, is the attempt that is being made to introduce free practice in the Canton of Zurich. A certain number of so-called "Nature-cure Societies" (Naturheil Vereine) who wish all illnesses to be exclusively treated by water, air, sunlight or electric light, electricity, massage, etc., in the most varied and oftimes curious forms, are seeking to upset the present law as regards medical practice. So far only men possessed of a Federal State Diploma, which can be obtained only after a medical curriculum of six years and severe examinations, have been allowed to practise the art of medicine. Now every effort is made to gain the vote of the public to allow any man whose own opinion is to qualify him to practise the art of healing, provided he prescribes no medicines, it being left to the certified medical practitioner to write recipes, or as these brave champions for the welfare of the country put it in their lectures and in print, "to poison their patients." The Medical Society of the Canton of Zurich has taken the necessary steps to instruct the public at large regarding this movement, which is so far spread that it has a chance of success, a success which would later on be bitterly rued perhaps even by the instigators, when left to the merciless hands of some uneducated quacks.

Professor von Herff, who occupies the chair of obstetrics at the Basel University, has published a résumé of his treatment of severe cases of puerperal fever. He recommends one or two uterine douches at the onset of fever and uses chlorine water exclusively. Serum treatment gave indifferent results, as we generally have to do with mixed infections. His experiments with intravenous injections of the salts of silver, which have a strong bactericidic effect even in the weakest solutions, gave him some striking results, which he attributes to catalytic influences on the tissue.

Dr. Theodore Zangger lately lectured before the Medica.

Society of Zurich on the detrimental effects railway trips to high altitudes have on elderly people. The special dangers such patients run, who may apparently be hale and feel healthy, are those of apoplexy and acute dilatation of the heart. Such accidents may occur while the travelers are at the altitudes in question (8,000 to 10,000 feet), but sometimes supervene only twenty-four to forty-eight hours after return to the lowlands. Dr. Zangger has seen a good many such cases. Further clinical evidence will doubtless throw more light on such avoidable accidents. No person over the age of sixty years should expose himself to rapid differences of altitudes without getting a medical opinion as to the state of his heart, blood vessels, and lungs.

Dr. Robert Haser of Muri, whose successful treatment of gallstones has made quite a stir among the medical public the last few years, has just published a scientific report on his first hundred cases. He reports 79 per cent. of the patients as cured, and apparently this "cure" has lasted at least one year.

This sounds most satisfactory, as the great majority of the patients have but operative interference to look forward to. After experiments stretching over a period of twelve years, he has arrived at a satisfactory combination of mercury (in small quantities), podophyllin, oil of melissæ, camphor, and anise. He recommends the patients to go to a sanatorium for a month or two, be carefully dieted, have saline baths containing CO_2 and have plenty of fresh air, and to exercise deep breathing as soon as they are fit to move about. He assures his confrères that under such treatment stones in the gall-bladder and ducts are dissolved, and that the tendency to new formation of stones is eradicated. He does not consider a patient cured unless able to stand the *usual* dietary after the cure. His theory is that, primarily, cholelithiasis is a nervous disease, not an infectious disease: that, primarily, the secretory (sympathetic) nerves of the liver suffer, that, secondarily, cholesterin is formed, then the bile becomes infected, catarrh ensues and bilirubin calcium is excreted; thereupon we have the formation of gallstones and localized hyperæsthesia.

LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

HEALTH REPORTS—A DISPENSARY IN MANILA—MANUFACTURE OF SERUMS AND VACCINES—MEDICAL DEPARTMENT OF THE PHILIPPINE CONSTABULARY—RAISING OF THE QUARANTINE—INSANITY AMONG THE TROOPS.

MANILA, February 10, 1903

THE report of the Commissioner of Public Health for the Philippines for the month of November, which has just appeared, gives the total population of Manila as 302,154, of which 223,900 were Filipinos, 60,680 were Chinese, 7,852 were foreigners, and 9,722 were Americans. There was a total of 1,035 deaths during the month, giving an annual death rate per thousand of 41.70; the death rate for the Filipinos was 52.52, for the Chinese 11.03, for foreigners other than Americans, 10.85, and for Americans, 8.76. This would seem to show that under proper sanitary precautions Americans in Manila should prove excellent life-insurance risks. The annual birth rate per thousand for the month was but 7.93, though it is stated that the return of births is incomplete. Of the 1,089 deaths during the month, eighty-one occurred in infants less than a month old, and 319 in those from thirty days to a year old. This infant mortality is very high, and due to ignorance, filth, and poverty. Five deaths were reported as having occurred during the month in individuals more than one hundred years old. The mortality was greatly raised by cholera, there being 256 deaths from this cause during the month. There were eleven deaths from typhoid fever, 11 from malarial fevers, 10 from dysentery, 34 from beriberi, 72 from pulmonary tuberculosis. Among the children, 198 deaths occurred from tetanus. There were 54 deaths among transients, which were not included in the statistics for Manila.

Prior to the outbreak of cholera, the death rate had been about 30 per thousand per annum. During the month of November, 35,316 units of vaccine virus was issued from the vaccine farm, of which 6,896 units were used in Manila. There were 134,996 houses inspected by sanitary inspectors during the month, and 47,217 reinspected; 39,192 houses were cleaned, 485 whitewashed and painted, and 800 disinfected; 954 cesspools and 31,544 yards were cleaned. There were 134 sanitary inspectors on duty. A large amount of refuse and dead animals were destroyed by cremation. There were 57 chemical analyses and 214 clinical examinations made in the Government laboratories. The leper census up to the end of the month showed the presence of 3,288 lepers on the islands, of which 2,004 were men, 1,074 were women, and 210 were children. The greater number of lepers occurred in Iloilo Province on the island of Panay, with 176 in the Province of Ilveos Sur, in northern Luzon. There were 43 Igorrotes and 220 Moros reported as having leprosy. The report, as a whole, showed that a large amount of excellent sanitary work was being carried out, and reflects much credit on the Commissioner of Health.

In a previous letter mention was made of the fact that one crying need of Manila and the islands generally was hospitals, dispensaries, and the other places where the natives might receive gratuitous medical treatment. Since that time the matter has been taken up by the Episcopal bishop, and a dispensary has been established in connection with the "Settlement House." The hours for the clinics are from seven to ten in the morning, and from three to five in the afternoon. The physicians in attendance are fifteen in number, of whom ten are American and five Spanish or Filipino. The clinics include general medicine, surgery, diseases of the eye and ear, skin, and nervous system, also obstetrics and diseases of women and children. The staff includes some of the best practitioners in Manila. That this dispensary will do incalculable good goes without saying. Under the Spanish administration, no effort seemed to be made to secure proper treatment for the indigent natives. The ecclesiastical orders did not a little toward supporting the paupers and orphaned, but their charities usually took the form of small weekly donations of money or food, and medical charities were not encouraged. It is to be hoped that the new dispensary in Manila may prove the entering wedge for the establishment of similar institutions throughout the larger cities of the islands.

The farm for the production of vaccine virus and the serum institute have recently been consolidated, and transferred to the control of the Director of the Government Laboratories. The present director of the laboratories, Dr. Freer, will return to the United States to resume his position as assistant professor of chemistry at the University of Michigan, on the return of the new director, Dr. R. T. Strong, from Germany, where he is now studying. Dr. W. E. Musgrave has been given a provisional appointment as the head of the Government Pathological Laboratory, in which he has served for some months as assistant, having previously occupied a similar position in the Army Laboratory. He is well qualified for the position, and will undoubtedly give full satisfaction.

A medical department for the Philippine constabulary, made up of about 6,000 natives with white officers, is now being organized. So far, four appointments of medical officers have been made, the appointees being ex-contract army surgeons or medical officers of volunteers, and others will follow as the service is organized. Medical officers are rated as Inspectors of the first-class, and will receive $1,800 per annum. Their duties will be such as will permit of outside practice, and their positions will be much like those of police surgeons in the larger cities of the United States. Hospitals will be established where the members of the constabulary can be sent for treatment. The medical service is to be outfitted with the same supplies and equipment as is now issued to the army, with which the constabulary may be called upon to serve. There will be a hospital corps attached to the new medical service, the privates of which are to be natives, specially qualified for this work. There is to be a grade of pharmacist having the pay of a second-class inspector, or $1,500 a year. At the outset these pharmacists are to be taken from the army hospital stewards, appointed fourth-class inspectors in the line at $1,000 per annum, and promoted two grades when transferred to their medical duties. As the force of 5,000 native scouts, now attached to the army, is to be incorporated with the constabulary as a police force, this will give a total of 11,000 men whose medical needs must be given attention, and which will require the services of a considerable number of physicians when this consolidation is accomplished. At present, the army authorities are looking after the professional needs of the scouts. One difficulty to be encountered in the medical care of the constabulary is that they are to be scattered in small detachments all over the islands, and it will be possible to maintain surgeons only in the large cities and at centrally located points, much as the medical service of the Northwest Canadian Mounted Police is now carried on. The development of the new service will be watched with interest and encouragement by army medical officers, since its methods, policies, and equipment are to be identical with those of the military service. That it is much needed is shown by the fact that in a recent fight with "ladrones" an American inspector died from arterial hemorrhage from a bolo wound of the forearm, which would have proved relatively trifling had a surgeon or trained orderly been at hand to apply simple treatment and dressings. Of the four surgeons already appointed to the constabulary Drs. Kneedles and Baker will have charge of the First District, with headquarters at Manila; Dr. Wheate will go

to the Second District, with headquarters at Tayabas, and Dr. Winslow has been assigned to the Third District, the headquarters of which are at Cebu. New districts will be made and new assignments ordered as the work of organization progresses. The new service will be much like the British Indian Medical Service, but will be wholly distinct from the army.

In view of the cessation of cholera in Manila and vicinity, outgoing transports will no longer be held at the Mariveles Quarantine Station for five days, as has been required for the past ten months, provided that none of the troops or passengers have come from infected points within the five-day period. Usually troops brought up from cholera-infected points in the south are held in quarantine a sufficient time to determine the presence of infection among them, and further quarantine of the Pacific transports is deemed unnecessary under present improved sanitary conditions. The first transport to go out under the new conditions is the *Sheridan*, which left February 5 for the United States with about 175 sick and insane on board.

There is no question but that service in the islands, with its monotony, isolation, and tendency to produce home-sickness to a certain extent favors insanity. It is true that the rate of insanity among the soldiers in the islands is no higher than that for the general population of the United States, but this comparison is misleading, as the soldiers are carefully selected for mental as well as physical soundness, and no person who manifests any tendency toward lack of mental balance is permitted to enter the service. The amount of insanity among the soldiers in the islands is not at all as great as the "anti-imperialists" would have the public believe, but it is still unduly high, and is much higher than it will be when the troops are concentrated, according to the present policy, into large garrisons, where their comfort will be greater and amusements for their benefit can be supervised and promoted. There is no question but that the abolition of the sale of beer in the army canteen has increased the proportion of insanity, as it has favored "beno" drinking among the soldiers, a habit which cannot be long indulged in without the production of maniacal delirium. The abolition of the sale of beer in the canteen—which has meant, in the great majority of instances, the abolition of the canteen itself as an institution, due to insufficient receipts to pay expenses—has removed a potent factor in the maintenance of health and discipline. This is especially noticeable in these islands, where the climate prevents recourse for amusement to hunting, fishing and out-door sports, mail is infrequent, troops are in small detachments, and garrisons are surrounded by shacks furnishing incentives to vices of all kinds, and the lowest types. If the members of the W. C. T. U. are judged in the hereafter by the results of their action instead of their good intentions, the results in the Philippines alone will give them much to answer for. Their preconceived theories have not harmonized with conditions as they actually exist over here—a fact fully recognized by all except themselves.

Sarcoma of the Tibia Treated by Evacuation; Recovery.—Ch. Monod and Macaigne sum up the history of this case as follows: The patient was a woman of forty-two years, with a tumor of the knee diagnosed as sarcoma. An *x*-ray examination showed the lesion to be at the upper extremity of the tibia, and limited by a bony covering. The bone was curetted and the patient recovered. The tissue taken away was a gravish rose white, of friable consistence, without juice. Histological examination showed that it was a sarcoma. The greater part consisted of fusiform cells, isolated or in groups. The presence of myeloplaques served to characterize the tumor. They were separated by sarcomatous bands, of which the protoplasmic covering was rounded, or fusiform or irregularly polygonal, while within were numerous nuclei, ovoid, or round and colored.—*Bulletins et Mémoires de la Société Anatomique de Paris*, November, 1902.

Tropical Abscess of the Liver, with Report of a Case.—Solomon Solis Cohen and John H. Gibbon present this paper. Although multiple abscess of the liver is usually considered of pyæmic origin, still the fact that about half of the liver abscesses occurring in tropical countries are multiple would incline one to the view that the amœba is more often than is supposed the cause of this variety. Spontaneous cure often results from rupture into the lungs. Unless there is immediate operation, intraperitoneal rupture is invariably fatal. The treatment of this affection is entirely surgical and consists in thorough opening and thorough drainage. The two recognized methods of operating in this condition are: (1) Immediate drainage, and (2) exposing the liver, allowing it to become adherent to the abdominal wall, and then opening it twenty-four or forty-eight hours later.—*The American Journal of the American Sciences*, Feb., 1903.

Progress of Medical Science.

The Boston Medical and Surgical Journal, March 19, 1903.

An Account of Dr. Thaddeus Maccarty.—Burnside Foster gives a history of the life of Dr. Maccarty, a New England doctor of pre-Revolutionary days. In 1775 he had the smallpox and was successfully treated by Dr. Latham, according to the Suttonian method, which was then, and still is, a secret form of treatment. Delighted with the results, Dr. Maccarty entered into an agreement with Dr. Latham, and himself administered the treatment in his practice. He also erected a smallpox hospital, which was in existence long enough to carry through 800 persons with the loss of only five by death. After this he carried on his regular practice. In 1796 he was called to a new and until then unheard-of mode of curing diseases—the celebrated tractors of Dr. Elisha Perkins. For two years his delusions in regard to their efficacy continued, but the tractors then began to lose ground, and soon sunk into disgrace and oblivion. Dr. Maccarty seems always to have been held in great esteem, in spite of his leaning toward secret methods of practice; he was appointed a justice of the peace, and a justice of the quorum. He died in 1802.

Lipoma Arborescens.—Charles F. Painter and William G. Erving report seven cases of this affection. These fatty growths are not very uncommon; they occur as overgrowths of the synovial villi of the joint affected, or as true lipomata that have pushed in from the subserous fat as the result of laceration of the fibrous capsule. The authors agree in the main with Stieda's conclusion as to these growths, namely, that there is a hyperplasia and fatty degeneration of pre-existing synovial tabs; that histologically, the appearance is that of a typical chronic inflammatory condition, with, in addition, a specific appearance in case of tuberculosis. In an unopened joint the diagnosis is not certain, the swelling, tenderness, limitation of motion and ability to palpate not being absolutely diagnostic. The prognosis of spontaneous healing and recovery of joint function are unfavorable, and treatment should consist of arthrectomy (erasion), or, when tuberculosis is present, resection of the joint. The authors differ from Stieda in giving tuberculosis relatively a less important place in the etiology, and they would urge the importance of the absence of the clinical evidence of joint disease as leading to the diagnosis of a non-tuberculous condition, and encourage exploration of the joint where any doubt exists as to the nature of the pathological process.

Journal of the American Medical Association, March 21, 1903.

Some New and Unusual Therapeutic Applications of Ergot.—A. T. Livingston advocates the use of ergot in insomnia associated with nervous affections, headache, eye and ear disorders due to vascular relaxation, pain in general from the same cause, morphine and opium poisoning, appendicitis, drug habits (especially opium and alcohol), delirium tremens, asthma, puerperal eclampsia, hystero-epilepsy and chorea, bulbar paralysis, and paresis, acute inflammations, typhoid fever, and angina pectoris. In all of these conditions the drug acts through the restoration to the normal of faulty vascular conditions. Ergot is useful as a preliminary to operations, and as a modifier or preventer of shock. In many of these clinical emergencies, the remedy must be used hypodermically. The author prepares the solution by dissolving one drachm of Squibb's extract of ergot in one ounce of 1-3,000 formalin solution. Distilled water should be sterilized and then the formalin added, after which the ergot is dissolved and the whole filtered.

Observations on the Mechanics of Digestion.—W. B. Cannon gives the name of "rhythmic segmentation" to the process by which, in the small intestine, the food is mixed with the digestive secretions exposed to the absorbing wall and carried forward. This muscular activity begins in the duodenum, in which a mass has accumulated after repeated relaxations of the pylorus. Suddenly irregular movements occur about the mass, and then, at regular intervals along its length, constrictions of the circular fibers separate the mass into a number of equal portions. Hardly have the constrictions thus occurred when similar constrictions begin to appear about the middle of each segment. As these new constrictions deepen, the first constrictions begin to relax. Finally, when the new constrictions have completely divided the segments, the first constrictions have entirely relaxed and the neighboring halves of the divided segments unite to form new segments in the region of the first constriction. Now these new segments are again divided by circular constrictions about their middle, and neighboring halves of these divided segments unite to make a third series, and so on. This

process of rhythmic segmentation of the food may go on for several minutes in the duodenum (at the rate of thirty divisions per minute in the cat), so that the food, coming from the stomach, becomes thoroughly mixed with the outpouring secretions of the liver and the pancreas. It is usual for the process to be brought to an abrupt end in the duodenum by active peristalsis. A peristaltic wave forms behind the mass of food and sweeps it swiftly forward through several coils of the intestine.

The Plantar Reflex in Epilepsy, with Special Reference to the Babinski Phenomenon.—This topic is considered by J. M. Keniston, who made, on thirty-five insane male epileptics, tests for the plantar reflex as follows: (1) 700 observations at varying intervals between seizures in order to establish a norm for each individual; (2) 1,088 tests made immediately after seizures, as soon as clonus had ceased, and (3) a similar number of tests made an hour later. In these 35 patients we found the individual intervallary reflex to be of the normal type—flexion of toes on both sides—in 10 cases; there was a marked extensor response (Babinski) in 7; no response whatever in 2; and in the remaining 16 cases a mixed response, *i. e.* right flexor, left extensor, 5; right flexor, left negative, 5; right extensor, left flexor, 2; and in 4 cases an irregular response, sometimes flexor, sometimes extensor, or varying mixtures of flexor, extensor, and negative in one or other foot, with no predominant type. The percentages were: flexor response, 28.57 per cent.; extensor response (Babinski), 20 per cent.; mixed response, 45.71 per cent., and entire absence of response in 5.71 per cent.

Medical News, March 21, 1903.

A Preliminary Report on the Venous Hum in Relation to the State of the Blood.—C. N. B. Camac has observed in certain cases a bruit in the vessels of the neck, together with normal blood. Normal blood has been frequently found in cases of marked pallor. He tabulates a number of cases, and concludes that the practical point to a clinician is that pallor, and even a cervical bruit, may not indicate anæmia, and that the blood should be examined to determine this point. If the suggestion that the vascular tone is faulty be correct, cardiovascular stimulants would be indicated, and not the exclusive administration of iron.

Pneumonia: An Infectious Disease.—J. O. Cobb declares that a careful study of the clinical histories of cases in large hospitals is convincing that the "cold" theory is untenable. It is a disease incident to overcrowding and caused much by man's own fault, because it could nearly be wiped out by careful details of ventilation and disinfection. It kills as many people as tuberculosis, and it is increasing rather than diminishing. It is a disease incident to overcrowding, and cold or dampness have nothing to do with its spread, though dryness is a great factor. It is appalling to note the stupendous death-rate and to see that nothing is done to check the spitting habit, which seems to be the only cause of its spread.

The Indications for Operative Interference in Intracranial Tension.—Frederic S. Dennis states that the treatment of intracranial tension is a new subject, and one to which he has given of late special study. He believes that operative treatment is indicated in many of these cases, and has employed this measure with most gratifying success. The indications for operative interference are in some cases perfectly clear, while in others the phenomena present would not justify so severe a measure. The greatest difficulty is to determine what the line of demarcation is between the cases that demand trephining or lumbar puncture and those in which the plan of expectancy can be adopted. Deep coma calls for immediate operation. In the absence of deep coma, the writer is in doubt as to the expediency of operative interference in less severe cases of intracranial tension. When there is a fracture of the skull, indications for operation are clear. It is in those cases of intracranial tension with no external injury that doubt arises. Cases of intracranial tension can be divided into two classes as regards operation interference. Those in which intracranial tension produces profound coma; those in which the tension is not sufficient to produce profound coma. Operation will save cases included in the first class that uniformly died under the expectant plan of treatment. Operation will save the cases embraced in the second class when the symptoms are gradually increased in severity.

New York Medical Journal, March 1, 1903.

Report of a Case of Epidemic Parotiditis with Fatal Termination.—The patient of W. J. S. Stewart was a sailor en route from Manila to this country. The disease developed in the usual manner, but no specially severe signs or symptoms were noted. In two or three days great restlessness developed with slight delirium. Breathing was difficult, resembling that of chronic asthma. The extremities were cool—not cold—and there was a faint trace of blueness beneath the finger nails. The face was pale, anxious in expression, and wet with perspiration, although the weather was cool. Having been propped up in bed with pillows and a back rest, he seemed to become more comfortable, and his respiration was apparently accomplished with somewhat less effort. At this time he complained of difficulty in obtaining his breath, and of sharp pain in the region of his heart, holding his left hand over his left breast the greater part of the time. While in this condition on the fifth day, he gave one prolonged gasp and died instantly. The cause of death was considered to be sudden heart failure, occasioned by the excessive strain of the difficult breathing.

The Treatment of Felon.—E. W. Lee places his patient in a recumbent position and advises a general anæsthetic, as the sufferer is generally worn out with pain and is nervously excited. The hand and forearm should be made as nearly aseptic as possible, and an Esmarch bandage applied. The hand is then placed on an aseptic towel over a hard substance and an incision made from a few lines back of the inflamed area to the tip of the finger, down, if necessary, to the bone. As all hemorrhages and oozing have been prevented by the application of the Esmarch, the extent of the disease can be clearly defined. All pus and sloughing débris should be cleaned out with peroxide of hydrogen, and the wound cavity washed with a 1 to 1,000 bichloride-of-mercury solution. With knife, scissors, and curette all diseased tissue should be removed: integument, cellular tissue, tendon, periosteum, and bone. Not a vestige of diseased tissue should be left, for it may be the cause of further infection. The wound should again be cleaned out with peroxide and washed with bichloride. The whole cavity should then be swabbed with pure carbolic acid, immediately followed by a washing with alcohol, which will prevent over-action of the carbolic acid. The wound is again washed with a 1 to 1,000 bichloride-of-mercury solution. The wound can now be closed and held in this position with a snug, moist, bichloride gauze compress over which a dry gauze bandage is applied; over this, rubber tissue, and over all, including the whole hand, cotton gauze and a bandage, the arm and hand being placed on a splint and elevated. In four or five days the dressing can be removed, and if the work has been thoroughly done, the wound will be found closed, free from discharge, and on the rapid road to recovery without further loss of tissue or constitutional disturbances. A similar dressing should now be applied. Four days more will find the parts united, and then the wound only needs a protective dressing until new epidermis and skin have formed.

American Medicine, March 21, 1903.

Influence of Marriage and Pregnancy on Diseases of the Heart.—M. J. Backenstoe declares that he should not offer serious objection to marriage in the absence of all cardiovascular symptoms of certain gravity, when the patient is willing to promise to observe the proper diet in the case of pregnancy. He thinks that milk not only exerts a preventing action on gravidocardiac symptoms, but also on the appearance of albuminuria. He advises a mixed milk diet, the milk being taken at the rate of two liters daily. He approves of this diet from the third month of pregnancy. However, cardiac lesions are aggravated by repeated pregnancies. In the case of existing hæmoptysis or marked dyspnœa, marriage should be disadvised. But even here one must not be too uncompromising, and the various circumstances which have given rise to these symptoms should be considered, and the effect of treatment be inquired into. The situation of the patient in respect to occupation and hygienic surroundings must also be considered. If conditions are all favorable there is no reason for objecting to marriage. However, the patient should be well warned and instructed in the precautions necessary for her to observe.

Excision of the Superior Maxillary Under Medullary Narcosis.—A. W. Morton has found that under the influence of medullary narcosis, analgesia about the mouth is as complete as in the lower extremities. Nor are there any more constitutional disturbances than when the analgesia is used for operations on the lower extremities. In the case here reported, carcinoma of the entire right jaw, the upper lip was divided near the middle line; the soft parts were raised and reflected outward, exposing the superior maxillary to its attachment to the zygoma; the hard palate and the nasal process was divided by a saw; the back part was separated with forceps and chisel, and the periosteum separated from the orbital portion. The mass was removed as well as the soft palate, and the cavity cauterized. The writer has used this form of analgesia in 929 cases, seventy-six of which were operations above the

diaphragm. This patient was free from pain and did not swallow any of the blood or allow any to pass into the lungs. The writer believes that the greatest field of usefulness of this method is for operations in locations where there is danger of blood and secretions entering the lungs.

On the Transportation of Cellular Emboli through the Thoracic Duct into the Lungs.—W. G. MacCallum describes a case of multiple hemorrhagic infarctions of the lung produced by the plugging of the branches of the pulmonary artery with masses of cells of the lymphoid type and larger mononuclear phagocytic cells. The cells must reach the veins and then the heart, to be propelled into the lungs, and this may occur in one of three ways: They may be poured directly into some systemic vein, or they may pass by way of the portal vein through the liver, or they may enter the thoracic duct and be thus carried into the subclavian vein. The last method seems the most plausible, especially as the liver does not show any great number of these cells in its vessels. It can hardly be doubted that the embolism of the pulmonary arteries in one of the cases reported here was due to the transportation of masses of cells derived from the lymph sinuses of the lymph glands through the thoracic duct into the heart, and thus into the pulmonary circulation. In the contents of the normal thoracic duct the small lymphoid cell is predominant, while eosinophile and neutrophile leucocytes also occur.

Philadelphia Medical Journal, March 21, 1903.

Trunecek's Serum, and Its Value in Disturbed Cerebral Functions Caused by Circulatory Changes, with Report of Twelve Cases.—Alfred Gordon arrives at the following conclusions: (1) The combination of the inorganic salts known under the name of Trunecek's serum may be a valuable remedy in some cases of disturbed cerebral function caused by circulatory changes. (2) Not only by hypodermic and intravenous administration, but also internally this remedy may give favorable results. (3) When the iodides, nitrites, and other means used in such cases are without avail, Trunecek's serum should be given a trial. Sometimes a combination of both may be necessary. (4) Several days—at least a week—must elapse before the desirable results can be expected. Finally, there are cases in which the remedy is absolutely useless.

Cryoscopy.—D. S. Grim concludes that: (1) Cryoscopy cannot replace, but only supplement, the older qualitative tests and microscopical examination of urines. (2) It is probably the most delicate test we possess in detecting and estimating the effect of therapeutic measures directed toward cardiac and kidney lesions. (3) It permits of reasonable accuracy in diagnosing renal insufficiency and the type of renal lesion present, though the examinations should be prolonged over a number of days; his conclusions coinciding with Lindemann's. (4) Uræmia cannot be diagnosed from the examination of the urine alone. (5) Cryoscopy of the urine from each kidney, obtained by ureteral catheterization, and especially when supplemented by the phloridzin and methylene-blue tests, becomes a very delicate and reliable test in determining a unilateral kidney lesion and the degree of insufficiency of the affected kidney. Because of an insufficient number of cryoscopic examinations of the blood, the "interchange" theory of Koranyi cannot be criticized by the writer.

A Case of Diabetes Mellitus in a Young Child.—James Hendrie Lloyd states that it is obvious that a mistake or oversight in diagnosis of this affection may readily occur in very young children. The symptom that usually attracts the attention of the mother is the excessive thirst. Failure of nutrition is also usually rapid, and a general appearance of ill health quickly supervenes. Polyuria is not so apt to attract attention as in older patients. In these young patients the progress of the disease is almost always very rapid, and the result seems to be uniformly fatal. In not a few cases there is a history of heredity. Injuries figure in the histories of a few cases. The essential cause, however, is just as obscure as in the cases of adults. The writer reports the case of a boy aged two years and two months. The grandmother was said to have diabetes, but this could not be personally confirmed by the writer. The child had undergone a surgical operation, and had been under ether for nearly an hour, only about ten days before the onset of the symptoms. Whether the operation and etherization acted like a shock or trauma is a matter of speculation. The writer appends a list of undoubted cases of diabetes mellitus in children under three years of age.

The Lancet, March 7, 1903.

An Unusual Form of Vesical Calculus.—The stone was removed by H. W. Page, by the suprapubic route, from an idiotic boy of seven years. Lateral lithotomy was attempted, but no stone could be felt by sounding. There was, however, a hard lump on the hypogastrium, and it was thought this that might be a calculus lodged in a bladder diverticulum near the fundus. The mass removed was about the size of a large walnut, and consisted of some ten to twelve layers of laminated, tough material in appearance like wash-leather and like the decolorized blood-clot from an aneurysmal sac. The layers could be separated without difficulty. In the center of the mass was found a soft friable nucleus of mixed urates and phosphates about as large as a kidney-bean. This was doubtless the origin of the trouble and round it blood had been deposited in laminæ which had gradually been decolorized. No bladder pouch was discovered, and it is not easy to account for the deposition of laminated blood-clot round a nucleus, subjected, as it must have been, to the perpetual wash of urine. After the operation the child was kept in a warm bath and recovery was uninterrupted. He very soon lost his pain and began to take as much interest in his surroundings as his idiot state would allow.

A Case of Acute Tetanus with Certain Points of Interest.—The patient of L. D. Saunders was a man of thirty-eight years, who received a lacerated wound above the left patella and several scratches on the hands and face, from a carriage accident. The wounds were properly dressed, but eleven days ater he began to show tetanus symptoms. Antitoxin was given, but without avail, and on the thirteenth day he died. The points of interest stated by the author are as follows: (1) The antitoxin apparently had no effect whatever on the course of the disease. (2) No premonitory symptoms were complained of before the onset of the disease on the eleventh day after the accident. (3) Although the pulse gradually increased in frequency the temperature was normal, and it only rose to 101.8° F. just before death. (4) The opisthotonos spasms were comparatively slight and unaccompanied by pain, and were only noticed a few hours before death. (5) The end came quite quietly and painlessly and apparently was due to sudden heart failure. The patient was quite conscious to the end, and was able to swallow his nourishment without much difficulty. At the time of the accident the patient was in good health and had no history of previous illness.

Hydatid Cyst of the Spleen.—F. R. Seager reports the case of a boy of eleven years with a swelling over the left side of the stomach. The mass became larger after eating and at night. The boy was in good health and had been accustomed to drink considerable brook water and eat freely of watercress. Examination showed a swelling of the size of a small orange, distinctly noticeable in the left hypochondrium, projecting from below the costal margin, with its center just internal to the nipple line. Palpation of the tumor, beyond giving the sense of a cystic swelling, revealed nothing to suggest its nature or as to which was the organ affected. The percussion note was resonant over the tumor. There were no increase in splenic or renal dulness, no pain or tenderness on manipulation, and no appreciable movement with inspiration. The urine showed a trace of albumin. The diagnosis was thought to lie between a hydronephrosis or a hydatid cyst of some part. Incision was made under an anæsthetic over the tumor, and on opening the peritoneal cavity the spleen at once presented in the wound, with two-thirds of its anterior surface occupied by a tense, shining, yellow-colored tumor, which fluctuated on palpation. This was tapped and fully half a pint of clear limpid fluid was drawn off. The wound made by the tapping was then enlarged and a thick cyst-wall was shelled out in the ordinary way. The wall of the cavity was then stitched to the skin, a tube was inserted, and the rest of the wound was stitched. The boy made an uninterrupted recovery. The cyst was single with no daughter cysts.

The Conditions Which Modify the Characters of Inflammation of the Skin and Their Influence on Treatment.—In the second Lettsomian lecture, H. R. Crocker considers the influence of toxin absorption, the nervous system, the seasons ingesta, drugs, gout, and pregnancy. He notes as the most distinctive skin lesion of pregnancy the so-called "herpes gestationis," which is now acknowledged to be a dermatitis herpetiformis, with a special etiology, as precisely similar eruptions may occur both in single women and in males. Its general behavior in relation to pregnancy is interesting. Once it has occurred in relation to this state it is almost sure to recur in every succeeding pregnancy. One of his patients had seven pregnancies in eleven years and it attacked her at each gestation. It tends to begin earlier and earlier in the pregnancy, until sometimes it is the first intimation to the patient of her condition. With exacerbations and remissions it then continues throughout pregnancy, and shortly after parturition an attack of explosive violence occurs, and then the attacks diminish in severity until they cease altogether in from three to six weeks. Some begin in the same month

of each pregnancy and may stop before parturition and may recur after it, and some begin just after pregnancy. They may also last for a very long time after parturition, or may even become chronic or recur without a fresh pregnancy. In one of his cases at the fourth attack the patient was found not to be pregnant but to have cancer of the cervix uteri. The same kind of eruption has even been known to begin independently of pregnancy, to disappear when this occurred, and to recur when the menses appeared again, but naturally this could not be called a herpes gestationis.

Rise of Blood Pressure in Later Life.—Omitting the rarer conditions, such as obliterating endarteritis, neuritic arteritis, and periarteritis nodosa, Clifford Allbut suggests three classes of the so-called "arteriosclerosis:" (1) The involutionary—common in old people, often hereditary, not necessarily or usually associated with rise of arterial pressure; the nature of which, intrinsic or extrinsic, is unknown but does not lie in high living. This kind may be vaguely referred to the "faltering rheums of age." (2) The mechanical—the result of long-persisting high-blood pressure of whatsoever origin. (3) The toxic—resulting from such causes as lead, alcohol, or syphilis; usually met with in younger persons, in some of whom the pressure rises, in others not. For reasons he elaborates in full, he considers this condition to be quite distinct from the granular kidney. He believes the great cause to lie in excessive eating, and does not think that alcohol alone with food will cause it. There are a few old men, who, usually of lean habit and inheriting longevity, are endowed with enormous and persistent energy of mind and body, and who have never denied themselves meat or drink, yet at threescore and ten or fourscore years have good arteries and a moderate blood-pressure, but such men are few; in most persons, as life slows down, the powers of expenditure and excretion fall within much narrower limits. The ordinary man must be warned—say, as he passes the age of forty years—to keep up muscular exercise in the open air, and to control his appetite. Many men eat and drink far more than they need for the day's work; they are supplied with food generously, without hunting for it; and annual blood-letting has gone out of fashion. As soon as high pressure becomes manifest rigorous diet, deobstruent remedies, and exercise, such as cautious hill-climbing under the careful regulation of the physician, are necessary, and necessary not only during a month, but also for the rest of the patient's life.

The Lancet, March 14, 1903.

Concerning Antistreptococcic Serum and Its Use in Malignant Endocarditis.—C. Ogle concludes: (1) That the gravest symptoms, combined with streptococcic infection, even of the blood stream, are not incompatible with recovery if treated by injections of antistreptococcic serum; (2) that this is true also in malignant endocarditis, but that here the chances are probably less favorable on account of the colony of micrococci involved in the vegetations in constant contact with the blood stream; (3) that in malignant endocarditis staphylococci are frequent, or a mixed infection of staphylococci and streptococci, and (4) that if an examination of the blood be negative it would be prudent, therefore, to use injections of antistaphylococcic together with antistreptococcic serum.

The Use of Salicylic Acid as a Preservative in Food.—C. J. Macalister and T. R. Bradshaw claim that the use of salicylic acid as a food preservative is perfectly proper, and that the popular hue and cry against it is without justification. They challenge the opponents of its use to bring forward a single instance in which it can be shown that bodily injury has resulted from its employment in such a manner, and they deny that in the proportion in which they have met with it in articles submitted to them for examination it could be taken by any rational beings to such an extent as to do them any harm whatever. They further maintain that the use of this substance enables manufacturers to place on the market wholesome, agreeable, and inexpensive articles of food which form an acceptable and beneficial variety in the diet of persons who cannot afford more costly luxuries, and which, above all, supply the place of intoxicating drinks. They take this position after mature consideration, and with, they assert, an adequate sense of responsibility.

A Case of Floating Kidney in an Infant.—The patient of R. Phillips was a male child whose initial symptoms of illness were an attack of greenish vomiting and collapse coming on a few days after birth. From these symptoms it soon recovered. Examination of the abdomen revealed a very lax and atonic condition of the walls, and there appeared to be a small oval tumor causing a prominence of the abdominal wall just below the ribs on the left side. Palpation showed that this tumor was the left kidney "floating" forward. It glided about readily within the abdomen and could be displaced forward so as to come in contact with the abdominal wall just to the left of the umbilicus. The right kidney was also "movable," but not "floating." Its movement was chiefly in a vertical direction, and the anterior and posterior walls of the abdomen could be compressed together above its upper extremity and the kidney thus held down. The patient had several subsequent vomiting attacks and convulsive seizures. The author is not prepared to say that these symptoms are due to the kidney abnormality, as they occurred regardless of the position in which the child was held.

Some Points in the Anatomy and Pathology of the Vermiform Appendix.—In the second Hunterian Lecture W. McA. Eccles states that many varieties of bacteria may be found within the lumen of the appendix, in the walls of the tube, in the lymph formed on its serous surface, in the adherent portions of omentum, in the peritoneal fluid, in consecutive abscess cavities, in distant collections of pus, and even in the blood and remote organs. They may be classified as follows: (1) *Bacilli*—(*a*) bacillus coli communis in its various forms; (*b*) bacillus pyocyaneus; (*c*) bacillus prodigiosus; and (*d*) bacillus tuberculosis. (2) *Cocci*—(*a*) staphylococcus pyogenes aureus; (*b*) staphylococcus pyogenes albus; (*c*) streptococcus pyogenes citreus, and (*d*) diplococcus pneumoniæ. As to the frequency with which the more common individual organisms are found, the following may be taken as a fairly accurate estimate, based, as it is, upon the combined results of the investigations of many authorities: (1) varieties of the bacillus coli communis, 94.0 per cent.; (2) bacillus pyocyaneus, 0.5 per cent.; (3) bacillus prodigiosus, 0.5 per cent.; (4) bacillus tuberculosis, 2.0 per cent.; (5) staphylococci, 1.5 per cent., and (6) streptococci, 1.5 per cent. The bacillus coli communis is the only organism which is commonly found alone in cases of appendicitis. Cocci are but rarely present by themselves, though they are more often found in association with the colon bacillus. Tuberculosis of the appendix may be primary or merely part of a general infection of the alimentary tract. In its primary form, which is decidedly rare, it is apt to be very chronic, producing signs and symptoms of a chronic appendicitis. In these instances the mucosa and the submucosa will ordinarily be the parts involved, the serous membrane frequently remaining free. Now and then there are seen instances in which connective tissue hyperplasia is the predominant anatomical feature of the lesion, giving rise to a mass which to the naked eye is very difficult to distinguish from a new growth. This hyperplasia is probably the outcome of a low virulence of the bacillus and a consequent disinclination to caseation, and a great increase of newly-formed connective tissue in place of it. Secondary tuberculosis of the appendix is by no means rare, and, as a rule, presents no marked signs or symptoms of its own presence, these being marked by those of the more extensive infection.

British Medical Journal, March 7, 1903.

Diabetic Coma Treated by Transfusion.—David Young reviews this case. The patient, a man of thirty-nine years, was from the first weakly and unable to stand heroic treatment by purging and hot-air baths. His pulse and general condition called rather for stimulants, and he responded to transfusion in a very remarkable manner. Although the coma was very severe in type, still the patient lived for nearly eleven days after its onset, showing marked improvement after each transfusion. It could always be given painlessly after a hypodermic injection of a weak cocaine solution. On the first two occasions normal saline solution was used, and the liquor sodii solution for the later transfusions. It appeared as if the patient would be tided over his attack of coma till pericarditis developed, and apparently caused his death.

Case of Rheumatic Fever Complicated by Chorea, Iritis, and Endocarditis; Recovery.—Fred. C. Forster reports this case. The patient was a girl of twelve and a half years, suffering with sore throat and slight aching pains in the right knee and along the right tibia. The tonsils were inflamed. Although she was put to bed, and ordered to have a strictly milk diet, a saline purge and sodium salicylate mixture, the next morning the right knee-joint was much swollen and inflamed, as well as the right elbow and left ankle. At the end of a fortnight the cardiac condition was satisfactory. But three days later choreic movements began to develop. This continued for four weeks, and as they began to subside iritis developed. For some time the patient was very ill. Shortly after the onset of the iritis, endocarditis developed. Cyanosis and œdema accompanied the dilatation, and the outcome for several days was doubtful, but she finally recovered.

The associations between rheumatic fever, chorea, iritis, and endocarditis are well recognized, but it is rare for them to occur consecutively in one patient.

Case of Apparent Secondary Abdominal Pregnancy in a Rabbit after Primary Rupture of the Uterus.—Kurt Kamann describes the condition which he found at the necropsy on a rabbit. There was a complete fetal sac in the abdominal cavity containing a full-time fœtus only recently dead. The sac was attached to a very vascular part of the great omentum which had been drawn out in the form of a pedicle. The placenta was on the wall of the sac opposite its point of attachment to the omentum, which was the only means of connection between the fetal sac and the mother. The internal genital organs were at some distance from the sac, and appeared to be free of any marked changes. On examination of the uterus by sections, the left uterine horn showed, microscopically, a tear in its wall, filled with fresh granulation tissue. This proved that the fœtus had not developed primarily in the abdominal cavity, but in the uterus, and that the full-time fetal sac, together with the placenta, had passed out through the tear in the uterine wall. The writer believes that its attachment to the omentum took place during the course of a gradual protracted rupture of the uterus, so that the fetal sac, becoming adherent to the omentum, received its blood supply from it before being completely expelled from the uterus. He compares these phenomena with the so-called abdominal pregnancy in the human female, believing that the Fallopian tube gradually ruptures and that the fetal sac, which is slowly expelled, becomes adherent to the neighboring abdominal organs.

British Medical Journal, March 14, 1903.

Sanatoria Plus Homes for Consumption.—W. Rushton Parker believes that if all consumptives could be treated in sanatoria for three months during the earliest stage of their disease, and taught how to preserve the health there regained, very few would reach the advanced stage so dangerous to the general community, and thus a great public benefit would be gained. Sanatoria might well be erected and maintained out of the rates for the general good. Not only sanatoria for the arrest of the disease in its early stage, but also homes for the isolation of advanced cases from the rest of the community are needed.

The Dietetic Treatment of Pulmonary Tuberculosis from the Point of View of Its Hæmatology and Histopathology.—J. J. Galbraith groups cases of pulmonary tuberculosis under two headings: Those in which the recuperative power of the system is sufficient to produce a reaction, capable when properly guided and sustained, of stopping the progress of the disease; and those in which the system is incapable of stimulation by the ordinary means and the disease progresses toward a fatal issue. The recuperative power itself also falls naturally under two headings: The physiological tissue reaction, the main factor in recovery, and the physical capability of the infected organ for repair. The former, in many cases, is sufficient to arrest the progress of the disease. If it be true that the leucocytes have a special antibacterial action, and that changes in them are the evidence of a reaction to poisoning, which may be common to all tissues, but is demonstrable only in the blood, then only those constituents of the diet which produce or favor this reaction need be in excess of the normal. The remainder is increased as the capability for making a proper use of it is gradually restored. Digestive leucocytosis is produced, not by the absorption of nitrogenous food indiscriminately, but by the action of the nuclear constituents, and is in proportion to the amount present. A diet mainly animal furnishes the largest amount of nuclein derivatives in proportion to the quantity taken, while, if properly administered, it throws least strain on the organism. One advantage of a meat diet, in addition to its directly curative value, is that it supplies organically combined iron, and renders the administration of other organic hæmatinics unnecessary. The percentage of hæmoglobin rapidly rises. From a histopathological point of view, rational dieting consists in furnishing a diet rich in the appropriate albuminous constituents. The special advantage of a meat diet in this relation is that, besides containing the nuclear bodies which have a directly stimulant action, it contains also proteids which have a high nutrient value. Sufficient fat and carbohydrate must be given to meet the physiological needs, and increased later, as metabolism and absorption improve, to the maximum which can be elaborated.

Münchener medicinische Wochenschrift, March 3, 1903.

Is Lupus Erythematoides a Tuberculide?—A. Gunselt negatives this question and reports a case of disseminated lupus erythemoides in which, upon autopsy, no tuberculous lesions were found to be present anywhere in the body. Including the cases hitherto reported this makes twenty cases of this disease which have been autopsied. In only nine of these have tuberculous lesions been present. On this basis it certainly cannot be claimed that lupus erythemoides is a tuberculide; that is a disease produced by the effects of tubercule toxin.

Gonorrhœal Cutaneous Ulcers.—Oskar Salomon and A. Blaschko report the case of a female in whom, while she was suffering from gonorrhœa, an ulcer developed upon the internal surface of the right labium majus. The ulcerated surface spread rapidly and produced an abundant secretion. Upon examination the latter was found to contain the gonococcus almost in pure culture. The identity of the organism was established by both microscopical and cultural methods. Later, the pus became contaminated with both streptococci and staphylococci. The ulcer completely healed in short time under applications of a 1-per-cent. solution of nitrate of silver.

Spinalgia as an Early Symptom of Tuberculous Infection.—Johannes Petruschky says that spinalgia (a susceptibility upon pressure of the spinous processes of any of the vertebra from the second to the seventh dorsal) is an early symptom of tuberculosis of the bronchial glands, and is often present when tubercular lesions in the lungs or other regions of the body are not present. Its value in the early diagnosis of tubercular infection is hence apparent. This symptom is not, however, always present. Its absence, therefore, does not negative tubercular infection. The above opinion is based upon the observation of seventy-nine cases of tuberculosis by the author. All but two of these reacted positively to tuberculin. All showed typical spinalgia upon examination.

Berliner klinische Wochenschrift, March 2, 1903.

Some Causes of Hay Fever.—G. Rosenfeld reviews the various well-known varieties of pollen that may cause this disease, and adds thereto one not hitherto mentioned, and which is to be principally found in the vicinity of Stuttgart. It comes from the plant known as the plantus occidentalis. This plant is in bloom from the middle of May to the first of July, and it is during this time that the disease is prevalent. The symptoms are similar to those of hay fever, as seen in other locations, and experimental observations have definitely shown that the pollen of this plant produces, in this locality, the disease.

Autolysis.—F. Umber reports observations which show that autolysis, as produced by autolytic ferments, is a process active during the life of the human organism. The presence of autolytic products was demonstrated in various fresh pathological exudates. Furthermore, such exudates, when placed in vitro, under conditions favorable for autolytic action, show, after a few hours, a marked increase in autolytic products, and a corresponding reduction in albuminoids. The difference of these results from those announced by J. Schütz is probably to be accounted for by the fact that the exudates used by Schütz contained few if any leucocytes, while these were very abundant in those employed by the author.

Deutsche medicinische Wochenschrift, February 26, 1903.

Etiology and Serumtherapy of Hay Fever.—Dunbar shows, by a series of experiments, that the special symptoms of this disease are caused by the action of the so-called pollen-toxin," "which is a substance obtained from the pollen of various grains and plants by a process of extraction. If this toxin in watery solution is inoculated subcutaneously or instilled into the eyes of susceptible persons the characteristic symptoms of the disease are produced. Unsusceptible persons (those who have never suffered from hay fever) are in no way affected by this treatment. A long series of observations has absolutely proven this statement. The author has produced a specific antiserum by the successive inoculation of animals with this toxin. Such an antiserum absolutely destroys the action of the toxin when the two are mixed in vitro. It also causes the symptoms produced by the toxin to rapidly disappear if inoculated subcutaneously or instilled into the eye of a susceptible individual shortly after such a toxin has been similarly introduced. In the above experiments the author used a pollen-toxin obtained from maize, and the antiserum was obtained by the inoculation of the same toxin. Further experiments have shown that a serum obtained by the use of one variety of pollen-toxin may be active against an infection with another variety, both in vitro and therapeutically. Thus, pollen-toxin from rye is neutralized in vitro by an antiserum obtained from maize, and the symptoms produced by the rye-toxin were fully subjugated by the use of the maize antitoxin. If a similar inter-activity between the other various varieties is found to exist, the problem of producing an efficient antiserum for general practical use will be greatly simplified.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

ANDREW H. SMITH, M.D., PRESIDENT.

Stated Meeting, Held March 19, 1903.

Typhoid Fever in Infants and Children.—A symposium on this topic was held under the auspices of the Section on Pediatrics.

The Occurrence of Fetal and Infantile Typhoid.—Dr. J. LOVETT MORSE of Boston presented this paper. He said that although much had been written on this subject, yet, on account of the inherent difficulties of diagnosis from both the symptomatological and the pathological standpoint, no satisfactory conclusions had been drawn from these writings. However, conclusions based on the presence of the Widal reaction and of the typhoid bacilli had made the subject more definite. It should be noted that abortion of typhoid fever occurred in from 50 to 70 per cent. of the cases.

Fetal Typhoid.—In considering intrauterine typhoid infection it was necessary to throw out all the cases reported before the discovery of the typhoid bacillus. The majority of the cases would be found to be far from conclusive. There were, however, fifteen cases, proved by autopsies and cultures to be genuine typhoid. Of these, ten were born dead or died at birth. There was no longer any doubt about the possibility of the infection passing from the mother to the fœtus through the placenta. The possibility of bacilli passing through the placenta had been proved experimentally by several observers, though there was still some doubt about whether this could take place through the normal placenta. There were only seven or eight reported cases of congenital typhoid. The fœtus must often die *in utero* as a result of typhoid infection. In twelve cases the organs were carefully examined. In four of the cases the spleen was somewhat enlarged; in one there were healed ulcers and enlarged mesenteric glands; in one there was marked swelling of the liver and hemorrhages beneath the capsule. The lesions of the intestine and mesenteric glands were not found in intrauterine typhoid unless the infant lived for some time after its birth. These differences from extrauterine typhoid were probably to be explained by the different mode of entrance of the infection; one was a primary, and the other a secondary septicæmia. The cases of adult typhoid without intestinal lesions were of interest in connection with the study of intrauterine typhoid, but it should be remembered that in the one infant living for three weeks after birth, there were quite distinct lesions of the mesenteric glands and in the intestine. The septicæmic nature of the infection accounted for the extreme mortality in fetal and congenital typhoid. There were many cases which proved that infection of the fœtus was not a necessary result of typhoid in the mother.

Infantile Typhoid.—A number of years ago there was considerable discussion as to whether typhoid fever ever occurred in infancy, and while this question was soon settled in the affirmative, there was much difference of opinion expressed regarding the comparative frequency of the disease in infants. Statistics in epidemics and in large series of cases apparently showed that typhoid was uncommon at the age of two years. The striking feature was the large proportion of them occurring in connection with cases in the same house or in connection with large epidemics, which suggested that infants only contracted the disease when there was considerable exposure. He had been able to find records of thirty-two cases of typhoid occurring in infants under two years of age, in which the diagnosis was undoubted. A positive Widal reaction was present in twenty-three, a bacteriological examination established the diagnosis in five, and in four cases both methods were employed. Of the thirty-two cases, sixteen died, giving a mortality of over 50 per cent. Rose spots were present in sixteen cases; distention of the abdomen in eleven; diarrhœa in nineteen, and constipation in five cases. Most of the cases had high fever. In the light of our present knowledge, the symptomatology of typhoid in infancy and early childhood was essentially the same as in adult life, and the disease was really and not apparently infrequent at this period of life.

The Occurrence of Typhoid Fever in Infants and Young Children.—Dr. J. P. CROZER GRIFFITH of Philadelphia read this paper. As regards the influence of age in the production of the disease, he said it was interesting to notice the change of opinion that had taken place in recent years. The belief was gaining ground that typhoid fever was not rare in infancy and childhood, although when compared with the number of cases met with in adults it was, of course, uncommon. He had reported eighteen personal cases occurring in children under two years and a half old. The principal cause of the relative immunity he believed to be the lesser frequency with which typhoid bacilli entered the intestinal tract. As compared with the symptomatology of the disease in adult life, the two chief characteristics in infancy and childhood were the less characteristic onset and course, and the tendency of the nervous symptoms to overbalance the intestinal symptoms. In general, it might be said that in infancy the disease was apt to be atypical in most respects; in early childhood the usual symptoms were greatly modified; in later childhood the symptomatology approached much more closely to those of adult life. The onset in infancy and childhood was apt to be slow and insidious, and children were often quite able to be brought to dispensaries, and, indeed, had to be observed for several visits before the diagnosis could be made. Vomiting was a comparatively common initial symptom in childhood, though it rarely gave much trouble. Epistaxis was not as frequent as in adults. Some degree of cough was common, associated with coarse mucous râles in the chest. Diarrhœa was a not infrequent symptom of the disease in the first eighteen months of life. The frequency in infancy, as distinguished from childhood, was probably due to the tendency of the intestine in early life to excite diarrhœa under slight provocation. Again, ulceration was known to be much less severe in early than in later life. It was a curious fact that during the present winter diarrhœa had been unusually prevalent in the Children's Hospital in Philadelphia. Abdominal pain was not infrequent. Rose spots were present in the majority of cases. The spleen was probably always enlarged. Desquamation had often been observed in his cases, but he had been unable to convince himself that it was in any way characteristic. The nervous symptoms were very marked, but the grave symptoms of the advanced typhoid state, so commonly seen in the adult, were not so often met with in the young child. There was generally a slight degree of apathy, which was characteristic, and there was apt to be delirium at night. Headache was common, but was not so severe as in later life. Meningeal symptoms were quite common, and often led to errors in diagnosis. The total average duration of the disease was from fourteen to twenty-one days. The temperature usually rose rapidly, and there was very little variation between the morning and evening elevation. It fell much more rapidly than in adults, and in some instances this fall was almost critical in type. Not infrequently there was a tendency for a moderate temperature to persist for weeks after every other symptom had disappeared. The solitary glands of the intestine were enlarged, elevated and of a pinkish color, and the mesenteric glands were usually decidedly enlarged. The tendency to ulceration of the intestine was not great. It was probably owing to this absence of severe intestinal lesion that the duration of the disease was short. The diagnosis of typhoid fever in early life was certainly difficult, and the value of the Widal reaction was inestimable at this

period of life. Meningitis must be carefully excluded. Enterocolitis could be usually distinguished after a little time. Influenza offered peculiar difficulties, because in both there was a continued pyrexia without adequate and obvious cause. The failure of the Widal reaction to show itself should not be looked upon as proof that typhoid fever was absent, because occasionally this reaction did not appear until very late in the disease. The various other infectious diseases might occur simultaneously with, or consecutive to typhoid fever. Noma was an unusual complication in children. Intestinal hemorrhage was quite infrequent, though he had seen one fatal case of intestinal hemorrhage in an undoubted typhoid fever in an infant of five months. Perforation was a very great rarity in childhood, yet he had happened to see four such cases, all in children approaching the age of puberty. Relapses were about as frequent as in adult life. The prognosis was good in children. Of 137 cases occurring during ten years in the Children's Hospital up to 1898 the mortality was only 2.9 per cent. In the period from 1898 to 1902 there were 295 cases with a mortality of 6.7 per cent., thus giving a total mortality of 5.32 per cent. In a series of 278 cases occurring in infants under two years and a half old the mortality was unusually high—51 per cent.

Treatment.—The bath method of Brand carried out with exactitude was not applicable to young children. Even a tepid plunge of 85° or 90° F. was often not well borne by older children. His custom was to employ sponging first, because it was often quite sufficient; if not, a graduated bath was used, beginning at 90° F. and cooling it down to 85°F. This was the safer plan. Sometimes a warm bath of 95° or 100° F. was useful, and the same was true of the abdominal ice-bag. Hydrotherapy should never be used in young children as a necessary routine, and the prolonged sponging of a struggling child was neither useful nor judicious.

The Symptoms and Etiology of Typhoid Fever in Children, Especially the Widal Reaction.—Dr. A. D. Blackader of Montreal read this paper. He said it was generally admitted that the symptoms of typhoid fever arose from a systemic poisoning brought about by an infection with the typhoid bacillus. The development of this bacillus in milk did not appreciably change the taste or appearance of the milk. Hand-to-hand infection was especially common among children. It was possible that flies might act as carriers of the infection. Out of 398 cases entering the Montreal General Hospital since 1900, 4 were below five years old, 19 were between five and ten, 32 between eleven and fifteen, 89 between sixteen and twenty years of age, and 92 between twenty-one and twenty-five years of age. After this age the numbers fell rapidly, so that only three of the patients were over fifty years of age. Similar statistics could be collected from the hospitals of any large city. It was urged that these figures were misleading, for the reason that young children were more apt than adults to be treated at home when sick. Typhoid fever under the age of five years was quite rare in private practice in Montreal. Of the 100 cases reported by him in 1900, 4 were under two years of age; 13 were over two and under six; 40 were over six and under eleven, and 43 were over eleven and under fifteen years of age. In his opinion, typhoid infection was most frequently met with in those children who exhibited a tendency to intestinal rather than gastric disorders. At times a double infection might occur, as, for example, of scarlet fever and typhoid. Comparing the onset, course and termination of typhoid fever in children and adult life, one was impressed by the mildness of the disease and its short duration. The onset was more frequently sudden in the child than in the adult, and sometimes simulated pneumonia, yet in about two-thirds of the cases the onset was even more vague than in the adult. The temperature curve was apt to be atypical, and the stage of continued fever brief. The disease usually ran its course in children in about three weeks, but the first few weeks of convalescence were often marked by sudden elevations of temperature. Abortive cases were not infrequent in childhood, the pyrexia terminating after the eighth or ninth day. He had been unable to find any record of typhoid fever running its course in children without fever. The mortality of simple typhoid in childhood was undoubtedly low. In his one hundred cases there was only one death, and in fifty consecutive cases under fifteen years of age taken into the Montreal Hospital, from 1900 to the present time, only three deaths occurrred. Deaths from typhoid in childhood were usually from some intercurrent affection, whereas hemorrhage and perforation were the chief causes of a fatal issue in the adult. In the great majority of cases the enlarged spleen could be palpated toward the end of the first week. Percussion often gave less definite results. With defervescence the spleen underwent rapid diminution in size. Gurgling in the ileocæcal region was of little importance, but sudden tenderness and sensitiveness could be made out in a certain number of cases in the second week, and should be carefully differentiated from appendicitis. The typical roseola could be found, if carefully looked for in the larger number of cases. It was generally present on the abdomen, though sometimes on the back, appearing between the tenth and fourteenth days of the illness. Evanescent exanthematas were met with in rare instances in cases complicated by some intestinal disorder. Desquamation was not generally noticed in this country. Large ecchymotic spots on the skin must be regarded as of unfavorable omen. Some bronchitis was generally to be found in children, if looked for, though it might not be evidenced by cough. It was a common sign of typhoid intoxication, and was of some diagnostic value. A high pulse frequency was the rule; only in long and severe cases did symptoms of actual cardiac asthenia develop. Transitory intermission of the pulse was, however, not infrequent, especially during the subnormal temperature. Dicrotism was almost never observed in children under ten years of age. The symptoms of intestinal irritation were seldom prominent in children. While a slight diarrhœa was present in the majority of cases at the onset, it quickly subsided under a careful dietary, and was frequently replaced by constipation. In his experience tympanites had been a rare complication. In a few cases pseudomeningitis might be an early symptom, but in these cases the slightly rounded abdomen, the palpable spleen, and, later on, the appearance of the roseola would generally clear up the diagnosis in a few days. True meningitis in the course of typhoid infection was extremely rare. Mental changes were also decidedly rare. Nephritis, as indicated by albuminuria and casts, was an occasional complication in older children, and it was not to be forgotten that the typhoid bacillus might develop in the urine and, in cases of retention, might set up a cystitis. True relapses were met with less frequently in children than in adults. Ehrlich's diazo-reaction was often present considerably earlier than the Widal reaction, and, when distinct, was frequently helpful, although, as was well known, it was by no means absolute in its indications. The Widal reaction should be sought for at least every second day in suspicious cases. In Montreal, where the dried blood method was first used on a large scale, it was the rule to employ a dilution of one in forty and a time limit of one hour. Definite clumping of the bacilli was considered essential. While nineteen of his cases had given the reaction on the tenth day, his experience was that in many instances the reaction was wanting until after the tenth day.

Typhoid Rare in Children of New York.—Dr. L. Emmett Holt said that he thought all pediatricians would agree that most of the cases which had given trouble in diagnosis were those in which there was a prolonged fever. There would be found a considerable number of cases of continued fever in which, after the illness had passed, the physician was still unable to make a positive diagnosis. The question

arose as to whether these were cases of typhoid fever or some other form of infection. He was disposed to think that a very small proportion of these cases were typhoid, but he considered it wholly unwarranted to assume that they were typhoid because there was an absence of the ordinary local inflammations. He was astounded to hear that Dr. Griffith had had such a large number of cases of typhoid fever in the Children's Hospital, because in his own hospital, during the past six months, he had met with only one case in a young child. This was the more remarkable because in the Babies' Hospital they were ever ready to make cultures and examine for the Widal reaction in every case of continued fever. In that hospital only three cases of typhoid fever had been found in fourteen years. It was evident, therefore, that the conditions under which Dr. Griffith had made his observations were very different from those existing in New York City. In the absence of the Widal reaction, after repeated examinations for it, the probability of the presence of typhoid fever was exceedingly small. In very young children typhoid fever appeared to be very much more a nervous than an intestinal disease; hence, the caution given by Dr. Griffith about looking for typhoid in cases suspected to be meningitis was of practical value. He had seen two or three cases in which the typhoid eruption was so profuse and prominent as to lead to the erroneous diagnosis of measles.

Dr. William P. Northrup said that in the New York Foundling Hospital, in a period of twenty-eight years, Dr. J. Lewis Smith, Dr. Joseph O'Dwyer, Dr. Roland G. Freeman and himself had not met with a single case of undoubted typhoid. From the literature of the world Dr. Griffith had only succeeded in collecting 417 cases of typhoid in children under two years and a half old, and of these there were 23 congenital cases. Personally, he had seen only six cases in children of two years or under, their ages being nine, thirteen, sixteen, twenty-two and twenty-four months, respectively. The subject was now in the hands of the laboratory workers, and it was in their power to settle this dispute.

Dr. H. Koplik said that the prevalence of typhoid fever in infants and children could not be determined as yet, because even experts differed as to what was essential for making the diagnosis. Koch insisted that it was necessary to examine the feces. In children over two years of age he was sure typhoid fever was much more prevalent than was generally supposed. In many very young infants the disease certainly often passed undetected. The mortality was about the same as in adults, and, as in them, varied very greatly with the prevailing type. The Widal reaction was of special value in those cases simulating meningitis and pneumonia.

Dr. Morse said he had personally gone over almost all of the literature of typhoid fever in infancy, and he was free to say that many of the cases reported by Dr. Griffith should not be accepted, and he did not think that Dr. Griffith would have accepted them had he personally examined the original reports.

Dr. Griffith insisted that the profession at large should be impressed with the fact that typhoid fever did occur at times even in young infants, for a great many physicians never even thought of this disease in such young patients, and did not look for the typhoid eruption. He had heard Dr. Northrup insist that one should not make the diagnosis of typhoid in infancy without the presence of the typhoid eruption, tympanites, diarrhœa and other characteristic symptoms, and yet, if this rule were applied to adult cases, many of the latter would be wrongly diagnosed.

Dr. Blackader said that the mortality, as stated by him, had been as he had ordinarily found it, and did not represent any exceptional type. He was aware that in France the mortality was placed much higher, though why he did not know. Certainly, in Canada, typhoid fever in children was looked upon as a mild disease.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, Held March 16, 1903.

Alexander Lambert, M.D., President.

Some New and Unusual Therapeutic Applications of Ergot.—Dr. Alfred T. Livingston, of Jamestown, N. Y., presented this paper. He said that it was almost thirty years since, as assistant physician in the State Insane Asylum at Utica, he had begun the use of ergot to modify the circulation in the brain in cases of insanity, especially those of melancholia. At first he had used al-almost exclusively the fluid extract of ergot, given by mouth, though some experiments were made regarding the hypodermic administration of the drug. In 1878, while practicing in Philadelphia, he had first become fully impressed with the therapeutic possibilities of ergot. He was called at that time to a man who had been retching violently and constantly for about four hours, and was greatly exhausted in consequence. The frontal vein was enormously distended, the pulse was full and bounding and the patient complained of much pain. Ergot was injected slowly, because experience had taught him that it was not wise to inject it as suddenly as morphine. By the time the syringe had been emptied the suffusion had disappeared, the retching and pain had ceased and the pulse was soft and but slightly increased in frequency. In a short time the man fell asleep and slept for six hours continuously. Some time afterward he had been called to the same man, who was in a state of great mental excitement because of the loss of a considerable sum of money. An injection of ergot was given with just as good effect as in the first instance. Ergot exerted a specific tonic effect on the circulation, especially on the vessels which were relaxed from lack of sufficient nervous impulse or from paralysis of the vessels from over-distension. Under these conditions the vessels were incapable of contracting against this pressure from nervous impulse alone. The drug acted on all dilated vessels wherever found, and in this way established equilibrium. It was contended that it raised the blood-pressure in the arteries, but if it did this it also diminished the pressure in the veins and capillaries; hence this objection was not valid if ergot were given in any ordinary rational dosage. The most important therapeutic property of ergot was its power to restore equilibrium and tone to the circulation.

Insomnia.—It was generally accepted that in natural sleep there was a diminished blood supply to the brain. Ergot was not only the most effective agent in insomnia, but the sleep following its administration was the most natural produced by any drug, probably because it produced that condition of the circulation which belonged to natural sleep. Many times patients had fallen asleep in his office after having received a hypodermic injection of ergot for the relief of a headache.

Headache.—Headache was probably the most common complaint of humanity, and it afforded a most extensive field for the therapeutic application of ergot, not only for immediate relief, but for the prevention of recurrences. Galvanization over the cervical sympathetic was a valuable adjuvant. The function of sight was often disturbed in persons suffering from headache, and he believed in many instances eyeglasses were prescribed when both the impaired vision and the headache were dependent upon a common cause.

Iritis.—The relief of pain in iritis from the use of ergot was both astounding and lasting. He wished the ophthalmologists would give ergot a fair trial in glaucoma.

Opium Poisoning.—To those who had not used ergot broadly, many of its effects would seem very strange. The author related a desperate case of morphine poisoning in which the respirations had sunk to two per minute, and strong faradization was used for two hours before the action of the current was perceived. However, on stop-

ping the faradization the patient promptly relapsed into deep stupor, from which he was most abruptly and completely aroused by the hypodermic injection of ergot. There was no relapse this time. He was so confident of this beneficial action of ergot that he insisted that this method could be relied upon along with the washing out of the drug from the stomach when it had been administered by that route.

Drug Habits.—He had also found ergot very useful in the treatment of opium and other drug habits, and had found it a most effective substitute for these drugs. He had frequently used ergot in pregnant women without any mishap, and there was good obstetric authority for this use of it when it was indicated during pregnancy.

Ergot was exceedingly useful in cases of acute alcoholism, in asthma, hysteria, hysteroepilepsy and catalepsy. In all these references to ergot it was to be understood that the drug was to be given only hypodermically. He had no confidence in its action when administered by the mouth, and moreover the ergot often seriously disturbed the stomach when so given. Many cases of general paresis were greatly relieved by ergot in the early stages.

Acute Inflammatory Diseases.—Ergot was certainly indicated in acute inflammatory diseases, and his practice had confirmed his opinion of its value in such disorders as meningitis, pneumonia, peritonitis, appendicitis, tonsillitis, erysipelas, erythema and inflammation of the veins and arteries. Among the troublesome sequelæ of influenza were local passive congestions of certain internal organs. These could be slowly but surely relieved by the persistent use of ergot.

Heart Affections.—He was of the opinion that too much attention was given to the heart in many cases and not enough to the conditions giving rise to the disturbed heart action. Ergot was ten-fold more valuable and efficient than all of the heart tonics and stimulants combined. He did not condemn this whole class of medicaments, but only their very common and improper use. For instance, it was clearly indicated that the load should be taken as much as possible off the heart in angina pectoris, and yet many excellent authorities in this field did not hesitate to condemn this use of ergot.

Ergot in Surgery.—Inflammations could only follow congestions, and the latter could only occur when the walls of the blood vessels in the wounded part had not sufficient tone. If there were lack of proper tone ergot would make good this deficiency. He had found the administration of ergot an exceedingly useful expedient in connection with the preparation of patients for surgical operations. Shock could be wholly prevented, or at least, greatly modified by the proper use of ergot. This often saved valuable time, which would otherwise be lost while waiting for reaction from shock. He felt that the most important part of his message was the statement that ergot would most effectively and surely secure that proper caliber of the blood vessels which would maintain a proper circulation in the body. Ergot would relieve pain just as effectively as did morphine, and without the congestion and disturbance of the vital functions which were associated with morphine.

Mode of Administration.—He had given considerable study to the mode of preparing the ergot and administering it. Many antiseptics had been tried with varying results. The mercurial had been discarded because of the irritation produced; iodine because of the tendency to the setting free of the iodine, and the carbolic-acid group because of its tendency to produce a turbidity which could not be removed by filtration. The solution ordinarily employed by him was Squibb's extract of ergot, one drachm dissolved in an ounce of water containing formaldehyde in the proportion of one to two or three thousand, or else a small percentage of trikresol. A syringeful of this solution, *i.e.* 25 or 30 minims, represented three grains of the drug. The solution should be made with distilled water sterilized by boiling, and the antiseptic should be added before dissolving the ergot. As a final step, the solution should be filtered. Experience had shown, though the reason for it was not clear, that a solution a few days old caused less pain and was more satisfactory than one just prepared. The minimum effective dose for an adult was fifteen minims, but it was frequently necessary to give two syringefuls. In extreme cases, as of uræmic convulsions, he would give four such syringefuls in such quick succession as practically to constitute one dose. One syringeful would generally relieve a bad headache, but if relief were not obtained the dose would be repeated in half an hour. The largest quantity of ergot that he had given in the twenty-four hours was ten ordinary syringefuls, or thirty grains of the solid extract. He preferred to give the injection in the left deltoid, but the space between the scapulæ was also good for making the injection beneath the skin. The injection caused some congestion and soreness in the part until a few doses had improved the tone of the blood vessels in the vicinity, when the patient would not longer mind the injections. He made it a rule always to inject the ergot solution very slowly.

Ill Effects.—He had never had an abscess purely from ergot. He had had a large experience with ergot, and yet had never seen a suggestion of ergotism or of other ill effects. With a proper solution and a sterile syringe and needle the ergot could be used freely until the desired effects were obtained, and the physician or surgeon need have no anxiety as to the outcome.

In conclusion, Dr. Livingston said he knew full well that as he did not come with the weight of medical authority there would be many disbelievers in his audience. He also knew that there was a strong prejudice against ergot itself, and that in some foreign countries it was difficult even to procure this drug, as it was looked upon as a rank poison. All that he asked was that his recommendations be given a fair trial, even though his paper seemed to indicate that he had a kaleidoscopic view of ergot, and that he used it as a music box upon which to play many tunes. All that was novel in the broad therapeutic application of ergot was the recognition of the varied inharmonious tones in the one chord he had mentioned, *i.e.* the disturbed circulation. Ergot was the master hand which, by its magical touch, would vibrate them in harmony and for health.

Dr. Frederick Holme Wiggin said it afforded him much pleasure to be able to say a few words in corroboration of the statements made in this paper. He had heard some of these statements made at a medical meeting last summer, and had been so deeply impressed by them that he had quickly tried ergot in his surgical practice. In the first case, one of laparotomy complicated by very strong adhesions, and in which after operation there was severe and dangerous intestinal paresis, he began the use of ergot hypodermically. The patient received ten syringefuls of aseptic ergot in twenty-four hours, and with the greatest improvement in the patient's condition. During the next day whenever the patient complained of pain or showed any sign of intestinal distention, ergot was administered. The patient made an excellent recovery. Since then he had had occasion to use ergot both before and after operation. It certainly had an excellent effect in controlling the nausea caused by the anæsthetic. A few weeks ago he had used it in a case of acute articular rheumatism of the ankle and wrist-joints. In a recent case of morphine habituation marked relief was afforded by the hypodermic use of ergot. In many other cases he had used the drug with equally good results.

Pulmonary Œdema.—Dr. S. W. S. Toms of Nyack said that he had had an important experience with ergot in two cases. About three weeks ago he had been asked in the middle of the night to see a brother practitioner eight miles away, who was said to be suffering severely from dyspnœa. Before his arrival another physician

had given digitalin, nitroglycerin, and strychnine. The patient was found to be deeply cyanosed, and had expectorated over a pint of frothy mucus. The dyspnœa was very distressing. He was a strong man, and had been busy all day with his practice. The attack had come on suddenly in the night, apparently provoked by anxiety over his daughter who was ill with typhoid fever. The speaker said he gave two syringefuls of Squibb's solution of ergot. In five minutes the breathing had been greatly relieved, but after twenty minutes, as the dyspnœa appeared to be returning, another syringeful was given. In a few minutes all cough and expectoration ceased, and in half an hour the attack of acute œdema of the lungs, due to disturbed compensation of the heart, had ceased, and he slept many hours.

Purpura.—The other case was that of a man of forty-eight, a grocer, having a good family and personal history. Some weeks prior to the present illness there was said to have been a rheumatoid condition, characterized by pain in the left shoulder-joint and radiating into the arm muscles, and not intensified by motion. This pain suddenly ceased, and was almost immediately followed by a rash over the lateral aspect of the feet and legs. The skin lesions were bright red petechiæ and ecchymoses into the submucous tissues, and they did not disappear on pressure. There was neither pain nor itching, and the lesions were not elevated above the surface. The head, face, and neck were exempt from the eruption. There were no erythematous manifestations. He had been taking a proprietary medicine largely composed of salicin. A careful inquiry into his dietary did not lead to any suspicion of scurvy, and the gums were perfectly healthy. There was no history of hæmophilia in the family. The attack referred to occurred on the evening of February 22. He suffered from violent pain in the left side, which suggested renal colic from hemorrhage into the kidney. It required two hypodermic injections of morphine to relieve it. There were no vesical symptoms, and the urine was then, as well as subsequently, normal. He was excessively nervous and erratic, and demanded immediate relief. There was slight rigidity of the abdominal muscles, and there was general tenderness on pressure, but especially over the region where the pain was first felt. The rash was not prominent over the articulations except the ankles. About the fourth day he was given a calomel purge. The pulse was about 100, full and tense. Two days later there were pretty free hemorrhages from the bowel with some vomiting of blood. This occurred for several days whenever he came out of the influence of the morphine. He was unable to take or retain any nourishment for over a week. The pulse then became quite weak, and averaged about 100. There was no elevation of temperature. On March 8 there was a slight indication of a recurrence of the rash about the ankles, and the next day it was quite marked upon the legs. The man was extremely nervous and weak. He was given a hypodermic injection of ergot at this time. The result was astonishingly prompt and satisfactory. He slept that night, and the next day the rash was fading. He received two injections daily for several days. On March 13 there was a marked recurrence of the rash, but without the former bad symptoms. This was attributed to some salicin that he had taken. This medicine was stopped and he improved. He had steadily improved since that time, and although still under treatment he was recovering rapidly. After each injection of the ergot the rash changed from a light red to a dark red, and by the next day the spots would be fading very perceptibly.

Dr. Charles Phelps was invited to take part in the discussion. He said that during the past month he had made some use of ergot, though not in the class of surgical cases in which it was most indicated. He had used it with admirable results in cases of arteriosclerosis. In some of these cases, occurring in old people who suffered from vertigo, the latter was quickly relieved by the ergot. The drug should prove of great service in cases of cerebral contusion, in which the mortality was considerable and was dependent upon hypermæia and œdema.

Dr. W. E. Ford of Utica said that he had been familiar with Dr. Livingston's work in nervous diseases and with his diagnostic ability in this field, and hence considerable weight should be given his statements, striking and novel though they were. The discussion was particularly interesting to him because ergot was an old and well-known drug. He had only used it himself in the field of gynecology, although formerly he had employed it with good results in nervous headaches. He was of the opinion that ergot was somewhat neglected in gynecology. Dr. H. N. Vineberg had called attention some years ago to the advantage of using ergot in cases of subinvolution and metritis, particularly where, as a result of this condition, the natural stimulus was absent and the mother found herself unable to nurse her child. He had found ergot very useful in such cases. While no doubt ergot might prove useful in many cases of weak heart, it was difficult for him to believe that it could take the place of strychnine, digitalis, and nitroglycerin. If increasing experience should make good the author's claims for ergot in this great field, this drug would certainly prove a most welcome and valuable addition to the physician's armamentarium.

Angina Pectoris.—Dr. Alexander Lambert spoke of his own recent experience with ergot. His first experience was in a case of angina pectoris in an old man with bad arteries, an aortic and a mitral regurgitation, and a very much damaged right heart. For some time amyl nitrite relieved him, but one time it utterly failed, and he then tried ergot. To his surprise, within about five minutes the patient's color was pink and his expression was better, and in ten minutes he was relieved. The same experience was repeated a number of times, although he finally died of a slow cardiac failure and not from an attack of angina pectoris. The case had seemed so desperate before the use of ergot that this result made a deep impression upon him.

Opium Poisoning.—His next experience was in a case of opium poisoning. Here the ergot awakened the patient, and kept him awake, after which recovery was uneventful.

Alcoholism.—The next experience was in cases of alcoholic "wet brain" in the alcoholic wards of Bellevue Hospital. For the past ten years he had had 800 or more alcoholic cases yearly under his care. He had tried everything that had been suggested to him in these cases of alcoholic wet brain, and yet always with a mortality of 95 per cent. Recently he had found such a patient lying puffing with a respiration resembling the Cheyne-Stokes' type. Ergot was ordered in doses of 15 minims every two hours. On his return the man was sitting up in bed smiling, and the nurse stated that after three hours the œdema had vanished and the man had become rational. He remained rational, and did not fall again into the state of serous apoplexy. There were ten cases of this kind, and seven of them were saved under the use of ergot. It should be remembered that these were not ordinary patients, for autopsies showed the patients of this class to have all sorts of remarkable pathological processes. He had also made use of ergot to relieve the intense tremor and dilapidation of alcoholics. He had used it extensively in this way, and had yet to see the alcoholic patient, even in Bellevue Hospital, who had not been sobered up in twenty-four hours by the use of fifteen minims of ergot every two hours.

Pneumonia and Pulmonary Congestion.—He had used ergot also in a severe case of alcoholic pneumonia following a three-weeks' debauch. The man had a most dreadful alcoholic tremor. He received nothing but ergot. The next day his temperature was normal, the tremor and the congestion of both lungs had disappeared and there was a small patch of pneumonia left in one lung. In four days this had disappeared and the man appeared to be perfectly well. About this time a woman who had con-

gestion of one entire lung from exposure during a cold snap was given nothing but ergot, and the following day the temperature had fallen to normal, the leucocytosis had disappeared and she recovered promptly. More recently he had observed four cases of pneumonia, three of them alcoholic, upon which ergot had not been previously used. In the middle of the night each of these patients developed general and marked œdema of both lungs, and the house physician, Dr. Gillette, reported that he did nothing but push the administration of ergot. In three hours they were comfortable, and all four recovered. Of course, he had seen cases of pneumonia in which the circulation was failing which had not been saved by ergot or by anything else. In one exceedingly severe case of asthma ergot did no good. The other day he had seen a peculiar case of poisoning from amylene hydrate as a hypnotic. The patient while in a stupor had reached out and taken the contents of the bottle, altogether nearly one ounce of amylene hydrate. Most of this was vomited. When seen by him six hours later she was still in a very deep sleep. She would awaken and speak a few words and then relapse into a remarkably deep sleep. The heart action appeared to be good. She was given two doses of ergot with the result that she promptly recovered.

Surgical Shock.—In still another case, one of strangulated hernia with organic disease of the heart, the patient was found in a state of intense shock. Although operation was urgently demanded the surgeon feared to operate because of the severe shock. The patient was given 15 minims of ergot. In fifteen minutes the pulse became quite good, and the anæsthetic was administered. At the completion of the operation the patient appeared rosy and in excellent condition, and he no longer showed any evidence of shock. Recovery was smooth and uneventful. Dr. Lambert said, in conclusion, that he had begun this use of ergot with a prejudice against it and no respect for it. He had lost this prejudice and now had a respect for it.

Prostatic Hypertrophy.—Dr. Edward Wallace Lee said that in cases of chronic hypertrophy of the prostate and in acute inflammations of this gland he had made use of ergot for many years, and was positive that the benefit from such medication had been very marked. Of course, the benefit in the acute cases might be questioned.

Dr. Livingston closed the discussion. He said that he had seen immediate and strikingly beneficial effects from the use of ergot in cases of cerebral concussion.

Pathological Society of Philadelphia.—At a stated meeting, held February 26, Drs. S. Solis-Cohen and David Riesman read a paper entitled "Ulcerative Endocarditis of Long Duration." Dr. M. H. Cryer presented two examples of lesions of the jaw. Drs. G. E. de Schweinitz and E. A. Shumway presented a communication entitled "A Study of the Corneal Lesions in Keratitis Bullosa." Dr. M. Howard Fussell presented specimens from a case of gallstones. During life a tumor had been present in the right hypochondrium, which was thought to be an enlarged gall-bladder containing gallstones, but which operation showed to be an anomalous lobe of the liver, while the gall-bladder was retracted beneath the liver, and it did contain gallstones. Dr. J. L. Carncross exhibited for Drs. W. S. Wadsworth and D. J. McCarthy specimens from three cases of cerebral aneurysm. In one symptoms of morphine poisoning, namely, embarrassed breathing of Cheyne-Stokes' character, with pinpoint pupils, were present, but on post-mortem examination an aneurysm of the posterior cerebral artery, with rupture into the lateral ventricles, was found. Dr. Carncross exhibited also a specimen of amyloid liver and kidneys from a case of hip-joint disease with spondylitis. The liver was enormously enlarged, while the kidneys were reduced in size.

New Instruments.

PORTABLE AND EASILY-ADJUSTED MECHANISMS FOR ULTRAVIOLET LIGHT.

By MARGARET A. CLEAVES, M.D.,
NEW YORK.

The results obtained by Finsen and his followers with ultraviolet light in the treatment of lupus vulgaris, alopecia areata and epitheliomas has created a widespread demand for simple and inexpensive apparatus for the purpose.

The Finsen tube by reason of its initial expense, as well as expense in operating and the long sittings required, is out of the question, save in isolated instances.

Many forms of light apparatus have been placed upon the market in the past three years, some of which are constructed so as to secure the maximum chemic action, others again of but limited actinic power. The use of unscientific apparatus minimizes the results and thereby depreciates the value of ultraviolet light.

From the beginning of my use of ultraviolet light, disassociated from the luminous and heat rays, in 1899, I have used a Finsen tube with glass lenses, one with quartz lenses, a special adjustment of a marine searchlight which is in daily use, and the two pieces of apparatus herein described.

The portability, simplicity of mechanism, and comparative inexpensiveness of the lamp, shown in

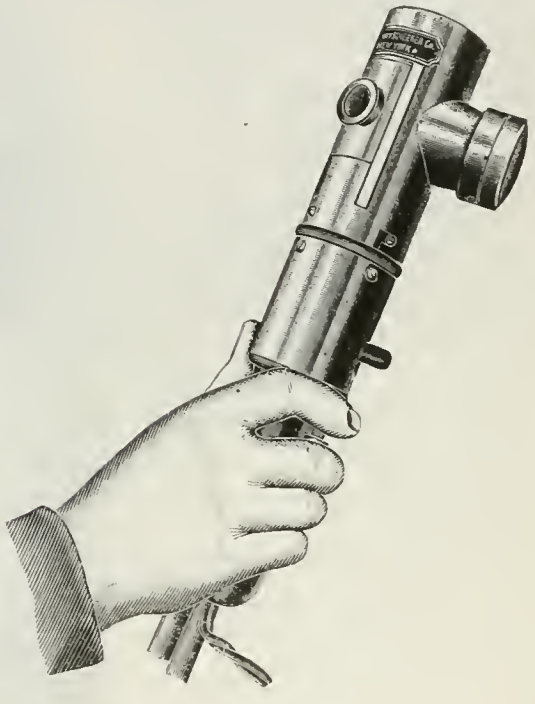

Fig. 1.

Fig. 1, renders it a desirable adjunct to the physician's equipment.

This lamp, manufactured by the Kny-Scheerer Co., N. Y., is modeled on the one devised by Dr. Sophus Bang, Finsen's assistant. It consists of a set of water-cooled iron electrodes instead of carbon. These electrodes are entirely enclosed in a cylindrical metal chamber which has two openings on the side. One of these has attached to it (by means of the ordinary bayonet lock), a water-cooling chamber and a set of quartz lenses. The other has a slide arrangement for holding a colored window, which serves the double purpose of allowing the operator to govern the intensity of light, or for treating such conditions as require a closer exposure to the direct rays of the arc. Through the hard rubber handle,

attached to the proximal end of the metal chamber, pass the conducting wires and also the rubber tubes for water circulation.

This apparatus is so constructed that the electrodes can be arranged for any intensity of light from 750 to 1500 candle power, and can be used on the direct circuit of 110 volts. The manufacturers are also at work upon one for alternating current circuits. A rheostat is included in the circuit, and is an absolute necessity in starting the light. After the arc is formed, the priming device should be released and the entire current can be turned on at the rheostat.

In the event of a coil being used for the *x*-ray, with suitable controller, the latter may be used for the lamp circuit, thereby minimizing the expense of the outfit.

Bang, in his experiments with an ordinary arc consuming 1375 volts of current per hour, found that it took four and one-half minutes to kill staphylococcus pyogenes aureus at a distance of 66 cm., while the lamp with the iron-cooled electrodes consuming the same amount of current at the same distance, less than four seconds were required.

The iron electrodes are particularly rich in the chemical rays of light, and by the water-cooling device a powerful actinic light is obtained, which can be used to within two inches from the arc itself. The spectrum of this lamp, while containing all the rays, is very intense and beautiful in the violet end. Photographically, it shows great actinic power, producing intense blackening of the bromide of silver paper in five seconds at a distance of twelve inches. Its bactericidal action, when consuming but one-third of the current, has been confirmed by experiments made by Dr. E. E. Smith and myself.

In a two minutes' application to a patient's face, sun-burn was produced, which lasted for several days, while a five minutes' application resulted in intense sun-burn with peeling of the skin. Its use has been followed in uterine cancer, by a relief from pain and irritation, as well as by a direct influence upon hemorrhage. Specula are made to use with this light.

In a case of recurrent epithelioma, two nodules on a woman's nose have been reduced fully one-half in three sittings of from three to five minutes each. The growth in this case was operated upon within the year, and a section examined at the time showed it to be an epithelioma.

In a case of rodent ulcer, the sensitiveness and soreness has been markedly relieved from a five minutes' exposure, and it is being used in this case in connection with the *x*-ray.

The second piece of apparatus is extremely simple and of immediate usefulness to every one possessing a high frequency coil or an influence machine. It was first suggested in 1901 by Görl[1] and Leduc.[2] Their mutual experiments demonstrated the richness of the electric spark, whether from a coil or an influence machine in ultraviolet light. Leduc found that photographic effects were obtained surpassing in intensity those of sunlight from the ultraviolet light thus produced, and that the rays produced intense fluorescence on a platino-cyanide screen without concentrating the beam, and in 1901 he suggested utilizing the influence machine as a source of ultraviolet light. He used these rays with a quartz compressor, as in the Finsen method.

The apparatus, manufactured by Van Hinlin &

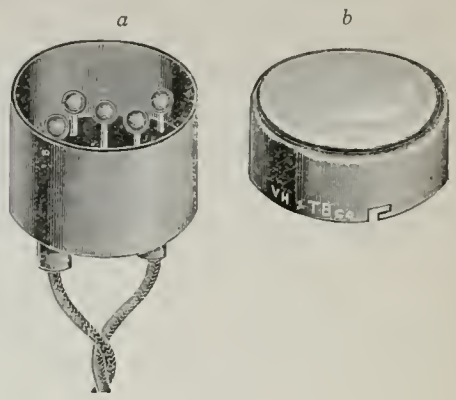

Fig. 3.

Ten Broeck, shown in Fig. 3, original with Görl, consists of five metal rods, preferably aluminum capped with small spheres of balls of similar metal. These rods are but an inch in length and the balls

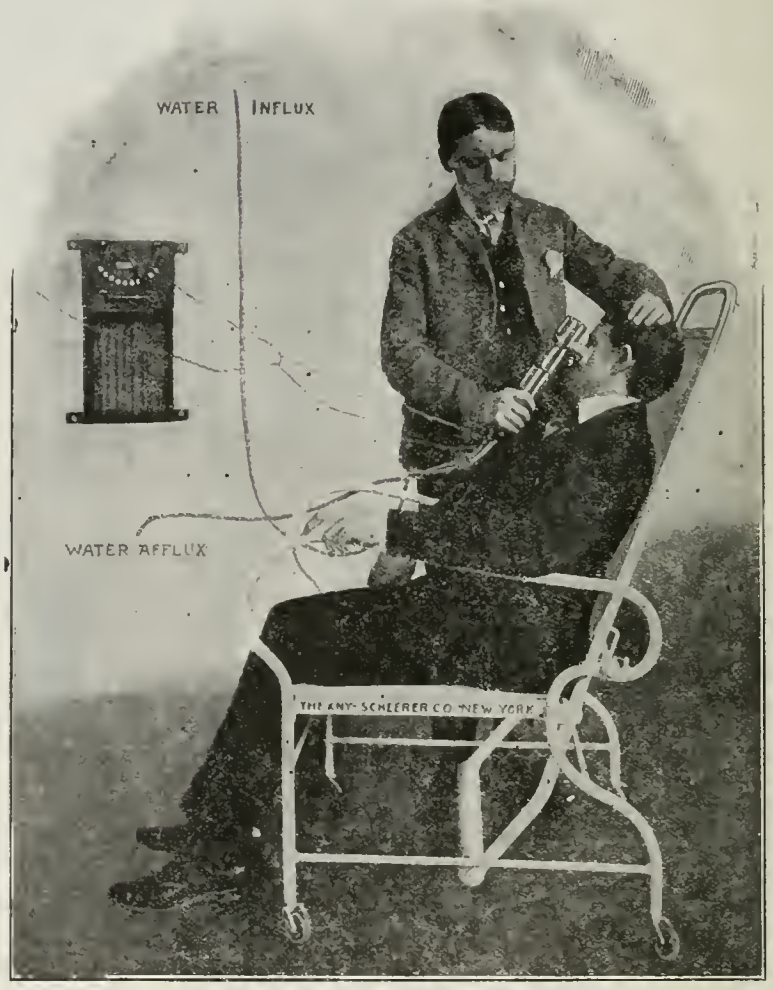

Fig. 2.

less than one-half inch in diameter. They are set at regular intervals in a hard rubber or mica base surrounded by a cylinder of hard rubber or mica, *a*. This in turn is fitted with a cap, *b*, containing a condensing lens. The spectrum gives all the colors, but the violet end is especially rich—not so intense as the violet end of the spectrum of the iron electrode arc, however.

Photographically, it shows very marked actinic power, but the darkening of the bromide of silver paper was not so intense with the same exposure and distance as with the arc.

Its bactericidal action remains unproven, although typhoid bacilli exposed, respectively, five and ten minutes were evidently weakened, as their development was delayed. With a thirty-minute exposure no action whatever was obtained on the staphylococcus pyogenes aureus. It emits a white light, is unaccompanied by heat or sensation of any sort, and, clinically, has been found to relieve sensitiveness and soreness in rodent ulcer and epithelioma, and also to produce the same sedative or soothing effect in uterine cancer as the iron electrode lamp. In it there is to be had an abundance of ultraviolet rays, not so great evidently as the arc, but capable of good when skilfully and judiciously used in a considerable range of pathology where the characteristic action of light vibrations are indicated. Better results are anticipated as a result of experiments in progress with a condenser containing a quartz lens. It may be used on either the primary or the secondary circuit of an influence machine. A specula is being constructed for uterine work fitted with a condensing lens of quartz. By means of the quartz lenses, in both the lamp and the condenser, the ultraviolet rays are permitted to pass, and the parts are rendered anæmic by pressure, as well thereby facilitating their penetration into the tissues.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending March 21, 1903:

	Cases.	Deaths
Measles	247	10
Diphtheria and croup	364	42
Scarlet fever	304	17
Smallpox	1	..
Varicella	123	..
Tuberculosis	341	164
Typhoid fever	70	13
Cerebrospinal meningitis	..	6

The Treatment of Fractures.—Borchard describes a method of treating fractures of the long bones, except the femur, which aims to accelerate the return to usefulness of the limb and especially to avoid the usual stiffness in the neighboring joints. According to his observations the sequence of events in an ordinary fracture may be chronicled about as follows: As early as the second day swelling and infiltration of the tissues immediately surrounding the fracture begins, the periosteum proliferates. and at about the tenth day a soft gelatinous mass has formed surrounding the fractured ends. Up to the fourteenth day no ossification has taken place and deformities may be corrected as easily as at first. From this time on the definitive callus formation begins, and by the twenty-fourth to twenty-eighth day this has attained such a degree of firmness that further displacement is impossible without the application of force. The outward swelling begins a few hours after the injury, increases and remains about stationary up to the fifth or sixth day, after which time it subsides again, so that the limb has regained an approximately normal contour at the tenth to fourteenth day. The author applies a wet dressing and a simple coaptation splint as soon as the patient comes under observation, and this is removed daily for massage, which at first is very light. This is increased in effectiveness day by day, the neighboring joints being also subjected to passive motion. The effect of this is to hasten the subsidence of the swelling, to diminish pain, and prevent muscular atrophy. On the twelfth day the fragments are accurately opposed, under anæsthesia if necessary, and a plaster bandage is applied. This remains until the twenty-sixth day when it is cut down, and the massage and passive motion are recommenced. In a few

days more the patients are allowed to walk, if the fracture was of leg, and it is found that the usual disability, œdema, etc., are very slight.—*Zentralblatt für Chirurgie.*

Bacteriological Examinations in Acute Suppurative Otitis Media.—W. C. Phillips enumerates twenty-one different microorganisms that have been found in acute inflammation of the middle ear. The streptococcus is now considered to be the most virulent and to possess the greatest migratory tendencies. This is true both as to the rapidity of its invasions and the severity of the accompanying symptoms. A few hours will sometimes suffice for an invasion of the attic, antrum, and mastoid cells. Current advice is to abandon the use of the ice-coil in streptococcus cases, and to operate after failure to relieve the symptoms by drainage and surgical cleanliness continued from twenty-four to forty-eight hours. The next most virulent type of inflammation, in proportion to its frequency, is that caused by the diplococcus intercellularis meningitis. Treatment should be the same as in streptococcus cases. The staphylococcus generally occurs in combination and most frequently with the streptococcus. The pneumococcus is frequently found, but is not to be considered especially virulent. It is probably the most frequent microorganism of all those enumerated.—*Archives of Otology.*

Malaria and Malignant Diseases in Hot Climates.—James Cantlie submits statistics concerning malaria and malignant diseases, which have been collated from the Colonial Office reports. They only show that malaria and malignant diseases may co-exist in the same communities, but we have no means of ascertaining whether the persons attacked by malignant disease were suffering from, or had ever suffered from, malaria. The question of malignant disease among native races remains a vexed one; and although these tables do not show whether we are dealing with Europeans or natives, it is a fact that over 90 per cent. of the hospital inmates are natives. In a hospital in the West Indies, British Guiana, for instance, natives form the principal number of occupants, while, in say the Government Hospital of Hongkong, Europeans form a large proportion of the patients. We require more exact statements as to the nationality of the population and the numbers of each nationality in our colonial hospitals before a conclusion can be arrived at.—*The Journal of Tropical Medicine.*

Free Spherical Thrombi in the Cavity of the Heart.—M. Kobsarenko says that only sixteen cases are known of this condition. In one case the thrombus was in the right auricle, in all the rest it was in the left auricle. In two cases there was no valvular lesion, while in the remaining thirteen there was stenosis of the auriculoventricular orifice in the left auricle. The size of the thrombi varied between that of a cherry to a hen's egg. Their consistency has been described in six cases only—one was soft, and the others hard. One of the authors mentions the existence of an endothelial membrane around the thrombus. As to the influence of sex and age, the thrombi were found equally in men and in women, and between the ages of twenty-five and forty years. The seventeenth case has recently been observed by Wyssokowicz at Kieff. The history of this case is given by the author.—*Russki Arkhiv Patologii, etc.*, November 30, 1903.

A Hint in the Application of the Colpeurynter.—Kurrer offers a suggestion which should make the employment of the rubber bag for the induction of labor a simpler matter. The ordinary method of filling such bags with a syringe requires constant supervision in order to prevent their premature expulsion as the cervix dilates. The author's method is, after introduction of the bag, to connect its tube with an ordinary irrigator filled with sterile saline solution and suspended at six feet above the level of the bed. This keeps the bag distended at a sufficient pressure and makes it keep pace with the relaxation of the cervix, so that it cannot be expelled until full dilation is effected.—*Zentralblatt für Gynäkologie.*

Modern Medical Education.—The whole scheme of modern high standard medical education appears to aim at the acquisition of huge masses of particular phenomena and observations to the crowding out of general laws and principles.—*Medical Press.*

Health Report.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ending March 21, 1903:

OBSERVATIONS ON THE PLAGUE IN THE PHILIPPINES AND INDIA.

By MAJOR CHARLES B. EWING.

SURGEON UNITED STATES ARMY; LATE CHAIRMAN OF THE BOARD FOR THE INVESTIGATION OF TROPICAL DISEASES, THE PHILIPPINES.

In this paper I shall only attempt to portray my short experience in observation of some fifty cases of bubonic plague, principally in Chinese, during the epidemic at Manila in the spring of 1901, with a brief description of my journey through India and the methods of plague treatment there. Three post-mortem examinations and some twelve or fifteen plague-stricken Filipinos were also seen at the Civil Government Pest Camp, and may be added to the list of cases observed by me. The Chinese were all confined in the Chinese Pest Hospital.

The difficulties in studying plague among Chinamen are very great; due in part to the national dread of a post-mortem, which, I think, must touch upon their religious belief, as well as to a very old Chinese custom that does not permit of any section of the dead whatsoever; hence post-mortems were not attempted by me. In a few instances I availed myself of an opportunity to cut down on the buboes and the principal blood vessels of cadavers, for the purpose of making cultures and blood specimens. Chinamen, I found, have a much greater dread of those dead of the plague than of the living suffering from this disease; hence I had a clearer field during the very limited opportunities afforded me in the dead-house.

My attention was first attracted to the subject of plague by a Circular Letter issued by the Board of Health of Manila, dated March 7, 1901, containing, as I thought, some misleading statements relative to this disease. The circular mentioned described pretty accurately the "black plague" of the middle ages, with the further statement that "in Manila the organism had been found in 90 per cent. of the bloods examined."

While in charge of the Pathological Laboratory of Santa Mesa Hospital, Manila, I had occasion to make some few blood examinations of plague patients, and these results not being in accord with the statement referred to by the Board of Health circular, I was anxious to determine by further observation to what extent my findings were correct.

My visits to the Chinese Pest Hospital extended over some two months and averaged several times weekly. During my early visits I found the pest-house in charge of Chinese physicians, and seemed only under partial control of the Manila Health authorities; but later—I think it was in April—a contract surgeon, U. S. Army, was detailed for duty at this institution.

The Chinese Pest-house is located on elevated ground in the northwestern suburbs of the city of Manila, very conveniently in close proximity to their well-known grave-yard, which, from its peculiar character and position on the side of a hill, is readily seen for long distances.

The Pest Camp, for treatment of Filipino plague cases, was separate and distinct from that mentioned and under entire control of the city health authorities.

The term "bungalow" might be used as expressive of the character of the tropical building used by the Chinese as a pest-house. It was a long, low building, raised by wooden piles some four feet above the ground; the walls and roof made of bamboo-frame-work, supporting nipa palm, with a floor of rough lumber. The roof was of the ridge pattern. Three doors served for entrance and exit, while some eight or ten windows, protected by bamboo-nipa blinds, gave light and air. The furniture was of the crudest kind, consisting of a few native cots; beds were not in general use, as most of the patients were found lying upon the rough floor. My visits were productive of some good in this respect, as the use of beds became more general, though some patients still occupied the floor up to the time when my calls ceased.

Besides solving the question as to whether examination of the blood in plague was of very much diagnostic significance, I was anxious to make some biologic studies of the pest organism. So, with this in view, I took, under antiseptic precautions, blood from the lobe of the ear in about fifty cases of plague, and after making smears upon glass slides, planted the blood in different media, such as agar, bouillon, milk, glucose agar, gelatin, etc., with a view to studying the developmental phases of the bacillus. I also made smears from the incised and suppurating buboes, as well as from the viscera of cadavers, seen by me, undergoing post-mortem.

I was able to detect the bacillus pestis in the blood of only about 3 per cent. of cases when the examination was made at all early in the disease, but growing the blood on culture media gave positive results in some thirty cases in which it was impossible to determine its presence by staining the blood-smears. The stain generally used was Löffler's alkaline methylene blue, lightly applied, because it was found that, if permitted to remain on the dried smear more than two or three minutes, the entire bacillus was stained, thus obscuring the capsule, instead of merely staining the poles and leaving the clear central space. Care was exercised also that smears were not overheated.

The percentage of cases in which organisms were found in the blood just before death was about ninety, and after death each of the twenty cases noted gave a positive result.

In the smears of some incised buboes the bacilli were readily detected, though in suppurating buboes pyogenic organisms were plentiful, and in continued suppuration, after a few days, the pest organism ceased to be found. I recall one case of this kind, in which a very extensive suppuration of femoral bubo had continued for several weeks, and the only treatment was a green leaf of some local plant applied to the part. No bacilli of pest were found in smears from this bubo at the time mentioned.

It is well to state that most Filipinos have more or less enlargement of the lymphatic glands

throughout the body, hence much care must be exercised in not confounding this with glandular swellings due to plague. I recall one woman with syphilis, and several men with venereal diseases, among the plague-stricken seen by me in the Chinese Pest-house, so that it is of the utmost importance that these cases be differentiated. One case of alveolar abscess in a Filipino, which was sent to the Pest Camp, is also brought to mind, in which some temperature and swelling of the submaxillary gland on the same side as abscess were noted. Leucocytosis of the polymorphonuclear variety was invariably found in all of the fifty cases examined, ranging from 8,000 to 50,000, commencing early and increasing in some cases as the disease progressed. The third corpuscle, the blood-platelets, were also increased markedly in number, associated with some anæmia and a moderate diminution in the amount of hæmoglobin. Some observers have found, experimentally, bacilli in the mononuclear leucocytes of the blood of the guinea-pig, though these have never been seen in the neutrophile.

Examination of the blood, then, may show at least two diagnostic features, the leucocytosis and the increase in the blood-plaques, or third corpuscles, which, even where no bacilli are to be found, serve to make the distinction as between malaria and typhoid fever. Early in the disease the blood is free from organisms, and especially, it seemed to me, the peripheral blood; hence it is not until the later phases of the disorder that the blood presents any very marked increase of organisms, which, twenty-four to forty-eight hours before death, becomes practically a pure culture. This late invasion of the blood by the pest microbe is quite in accord with the pathological processes taking place in the body in the bubonic variety of plague, when septicæmia or bacteræmia has usually developed, and, according to Cohn and Albrecht, the secondary buboes are being formed in different parts of the body.

I have nothing to add to the present stock of knowledge as the result of my brief bacteriologic study of the pest organism. It was some satisfaction to verify, in part at least, the work of eminent authorities in this very interesting domain of inquiry. In concise terms, then, the organism is to be found as to its

Origin.—In the lymphatic glands or buboes, and in some cases in small numbers in the blood, where it may occur singly, in pairs, clumps, or short chains. Authorities have found it in the sputum in the pneumonic form of the disease, as well as in the urine and fæces.

Form.—A short, thick bacillus with rounded ends (*cocco-bacillus*). At times it forms chains of from four to six cells. The organism is subject to great variation in form, and at times is surrounded by a capsule. Size is determined by the media in which it is grown. It is much shorter and plumper from blood, and capsule thick, but in media, bacillus is larger and capsule not always made out. I noted involution forms particularly on dry agar-agar, where the pyriform seemed to be the most strikingly characteristic. These vegetative forms are said to be mostly seen in the presence of antiseptics, mercury, salt, etc. Haffkine found them particularly numerous in 3 per cent. salt water agar.

Mobility.—I could detect no free movement in hanging drop, although I noted the marked Brownian motion. Kitasato alone holds that bacillus is actively motile. The organism is said by Gordon to possess one or two flagellæ.

Sporulation.—Spor formation not observed by me.

Staining.—It stains readily with most aniline dyes. That preferred by me is Löffler's alkaline methylene blue. Aovama says bacillus from blood is stained by Gram, but from other parts of body the organism is decolorized by this method, hence it is not applicable. All other observers hold that Gram's method decolorizes bacilli from every part of body. The bipolar effect and the capsule are only seen in fresh specimens from the body, and not observed in organisms growing on the various culture media. The beaded appearance has been observed in threads, and particularly in bouillon. The pyriform, large coccus, torula-like and other involution forms do not, as a rule, stain well.

Growth.—Is slow and not very abundant. Usually slimy—the cultures dying readily.

Plates.—The bacillus is essentially aerobic; that is, grows best in an atmosphere of oxygen, and an aerobic only in gelatin. Agar shows small, white transparent ground glass colony. Under the microscope colony is granular, of yellowish tint and darker in center than about the edges. On gelatin the colonies are small, round, sharply bordered, finally becoming granular and brown in color.

Stab.—Stab-cultures show very light white growth along line of needle puncture, spreading but little on surface. Streak culture on plain, neutral agar-agar shows whitish, slimy growth, made up usually of discrete colonies—in twenty-four hours the water of condensation is turbid, with slight sediment at bottom. Less growth found in two-per-cent. glycerin-agar. Blood serum yields good, but potato, poor growth. Bouillon: Organism grows very characteristically here, the liquid remains clear, while the granular, slightly flocculent growth develops just under the surface of the fluid and on walls of vessel. The stalactite growth is the most characteristic. The addition of 2 per cent. peptone and glycerin to bouillon makes a good media. In this soup all the bizarre forms are seen, and streptococci, like threads, are noted. Acid is produced in bouillon. Milk is not coagulated. There is no indol reaction in peptone solution.

Oxygen Requirements.—Bacillus is aerobic, grows on most media, in an atmosphere of oxygen best, and only as a facultative anaerobe in gelatin; that is, while it grows best in presence of air, it may grow, though less abundantly, in the absence of oxygen.

Light.—Direct sunlight destroys it in about three hours; it has been kept forty-five days on sterile paper in the dark.

Temperature.—Grows best at ordinary room temperature; cold has no effect; prolonged exposure to 32° C. unfavorable; an hour at 70° C. kills completely, as shown by Haffkine. Kitasato killed bouillon cultures of the bacillus with a temperature of 80° C., and in a few minutes with steam at 100° C.

Gelatin.—Bacillus does not liquify this medium.

Aeorgenises.—Organism is not a producer of gas—no effect when grown in glucose agar.

Attenuation.—The cultures of bacillus pestis generally lose virulence on artificial media, and organisms from convalescents are said to be non-virulent. The case of the Ann Arbor medical student is a very good illustration of the latter statement. Virulence is increased by passing through animals, or by the collodium sac method. The former was the only method in vogue until the collodium sac method was introduced a very few years since by Metchnikoff, Roux, and Salimbini. This, however, requires very delicate bacteriological technique for success. My experience shows that it is very difficult to keep the pest bacillus alive on the ordinary culture media used, unless this is alkaline in reaction and great precautions are taken to protect growth from light.

The moulds grow so luxuriously in the tropics, and are so resistant, that the ordinary test tube and Petri dish, when used under the usual bacteriologic conditions, hardly form proper receptacles for growing this organism. Again, the difficulties in the Philippines are further increased in the matter of making culture media by finding there water organisms so very refractory to heat that the autoclave (where heat is used under pressure) is absolutely necessary in sterilizing the culture media, the ordinary Arnold sterilizer not generating sufficient heat to kill these very resistant forms. I recall one, a drum-stick organism, which resembled the bacillus of tetanus in its morphology, and resisted a temperature of 70° C. for fifteen minutes.

While most of the plague cases seen by me were of the bubonic type, I recall a few somewhat out of the ordinary; one of these, of cutaneous plague, broadly speaking, in which the chief lesion consisted of a large pustule, or an aggregation of small ones, located on the right lumbar region of the back. It was some two and a half or three inches in extent, irregular in size, and originally contained pus. An irregular, granulating surface was that noted when I last saw the case. There were no enlargements of the lymphatic glands noticeable to the eye. The bacillus pestis was demonstrated in the blood. These pustular cases are rare. The patient, a Filipino woman, aged about thirty, recovered.

I have notes of several cases, among Chinamen, in whom the femoral buboes had broken down, leaving large, suppurating cavities, extending to the bone; neither of these gave a showing of the organism on smear, except when suppuration first commenced. These great, gaping, suppurative cavities are graphically portrayed by DeFoe in his *Journal of the Plague*, which disease ravaged London in 1665.

Of the post-mortems observed by me at the Pest Camp, I have notes on two cases which are illustrative of the characteristic lesions found in plague of the bubonic type. The case of a girl indicated that the portal of entry was at some point in the upper part of the body, as the primary bubo of the first order was located in the right axilla; no visible enlargement of the post-cervical or inguinal glands were noted, and none determined by palpation. The autopsy was only partial in this case, and was made to verify diagnosis of plague, when the microscopical examination had given a positive result.

The age was apparently about seventeen years; height, five feet five inches; hair and eyes, brown; weight about 120 pounds. Rigor mortis present; eyes dilated equally and normal. Lungs showed hypostatic congestion. The axillary lymphatic glands of right side showed swollen mass, two by three inches in size, with marked œdema and hemorrhage into adjacent tissue; the surrounding tissue much swollen; heart seemed to be normal in size, though minute hemorrhages visible to the naked eye noted on anterior surface of the ventricles. Liver was found to be enlarged and capsule adherent. No visible enlargement of post-cervical, left axillary or inguinal glands of either side and none found upon palpation. Serous surfaces generally ecchymotic and mucous membrane of alimentary canal hyperæmic.

Dissection of the region of the right axilla showed these glands to be enlarged, œdematous, and hemorrhagic, with peri-glandular infiltration extending into the surrounding areolar and fatty tissues. On cut section of the lymphatic gland, the substance bulged out, was œdematous, more or less hyperæmic and hemorrhagic; soft in the center, due, I think, to coagulative necrosis.

Am convinced that a further dissection would have shown a chain of second-order buboes extending from the axilla into the chest, along the blood vessels, presenting various degrees of hemorrhage, and probably carrying the infection by a backward flow of lymph to the cervical and glands of opposite side of body.

I am satisfied that this was a case of bubonic plague, in which the septicæmia (bacteræmia) was developed rapidly, before, in fact, buboes of the second order were formed. The microorganisms, as stated, were found in the blood. This patient died within twenty-four hours after entering the hospital.
